slippage in replication, but the role of MMR proteins in maintaining genomic stability is much greater. The ability of these protein complexes to recognize mismatches also allows them to inhibit recombination between heterologous sequences that share homology. For example, it was noted over 10 years ago that MMR-deficient cells show increased maintenance of telomere length by accelerated recombination events involving related telomere repeat sequences (28). Similarly, data from model organisms show that MMR-deficient cells demonstrate increased deletion and duplication events; again, secondary to the loss of this mechanism to inhibit recombination between heterologous repeats (29). Thus, the cancer phenotype seen in either the dominant or recessive condition may result from increase in several different types of genomic instability when mismatch repair function is lost.

## 42.5 DISORDERS ASSOCIATED WITH DOUBLE STRAND BREAK RECOGNITION AND REPAIR: ATAXIA-TELANGIECTASIA AND RELATED CONDITIONS

Children with ataxia-telangiectasia (AT) first develop truncal ataxia during early years of childhood, which

is progressive, eventually becoming wheelchair dependent (30). The disease name derives from the neurologic problems as well as oculocutaneous telangiectasia that is typically first apparent in the conjunctivae between the ages of 3 and 5 years. Individuals with AT have elevated alpha fetoprotein (AFP) levels, which can be helpful in making a diagnosis. AT is an autosomal recessive disorder due to inheritance of biallelic inactivating mutations of the *ATM* DNA damage response gene. Patients with AT have a significantly increased risk of leukemia and lymphoma as well as some increased risk for other tumor types (30). Women heterozygous for *ATM* mutations have an approximately twofold increase in risk of developing breast cancer during adulthood with no other clinical features of AT (31,32).

The cellular phenotype associated with AT is increased killing of lymphocytes (or immortalized lymphoblastoid cells) in response to ionizing radiation exposure. This quantitative assay is used as a clinical diagnostic test for patients suspected of having AT or related disorders (33). Radiation sensitivity exhibited by AT patients highlighted the important role that ATM plays in mediating the DNA damage response to double strand breaks (DSB), including DNA repair processes and cell

**FIGURE 42-4** Recruitment of DNA damage response proteins to a DNA double strand break. Prior to DNA damage, ATM exists as an inactive dimer. Following the induction of a DNA double strand break, ATM undergoes autophosphorylation, producing active ATM monomers. ATM and MRN (comprising MRE11, RAD50, and NBS1) are rapidly recruited to the site of the DNA double strand break. Upon recruitment, ATM phosphorylates MRE11, NBS1, and H2AX. The phosphorylation of H2AX leads to the recruitment of MDC1. MDC1 is phosphorylated by ATM and phosphorylated MDC1 serves as a docking site, recruiting the RING-finger ubiquitin ligase RNF8. RNF8 monoubiquitinates  $\gamma$ H2AX, resulting in the recruitment of 53BP1, BRCA1, and RNF168. The RING-finger ubiquitin ligase RNF168 maintains the ubiquitinated status of  $\gamma$ H2AX, aiding in the stabilization 53BP1 and BRCA1 at the break site. (From Derheimer, F. A.; Kastan, M. B. Multiple Roles of ATM in Monitoring and Maintaining DNA Integrity. *FEBS Lett.* 2010, 584, 3675–3681.)

cycle checkpoints (34). ATM protein resides in cells as a homodimer that is inactive (Figure 42-4) (35). After DNA damage or alteration in chromatin structure, the homodimer is disrupted and kinase function is activated. ATM phosphorylates a very large network of regulatory proteins that mediate recognition and repair of DNA lesions, including p53 and BRCA1 (36). Disruption of this network is thought to result in genomic instability and cancer development. Patients with AT who develop

cancer require substantially modified treatment regimens due to deficient DNA repair activity, which is manifested by clinically significant cytotoxicity in response to chemotherapy and radiation treatments (33). The link between ATM deficits and neurologic disability is much more complex and thought to potentially result from excess apoptosis in neurons that accumulate DNA damage, or perhaps accumulation of reactive-oxygen-species-mediated damage in neurons (6).

Defective double strand break repair (DSBR) also impacts the metabolism of DSB, seen as intermediates of normal VDJ recombination in lymphocytes. For example, repair of coding ends, where ATM normally accumulates, is thought to be delayed or defective in lymphocytes of AT patients (37). Abnormalities in VDJ recombination is thought to explain the lymphoid abnormalities seen in AT patients including: immunodeficiency with sinopulmonary infections, low levels of IgG, and prevalence of t(7;14) translocations in stimulated peripheral blood karyotypes.

In addition to ATM itself, there are a number of proteins required for DSBR, and the deficiency of these results in a series of related disorders (Table 42-3). The recombination-activating genes *RAG1* and *RAG2* play an important role in initiation of VDJ recombination. There are several autosomal recessive disorders that result from inheriting mutations in either of these two genes. Patients with two truncating mutations, e.g. nonsense or frameshift mutations, demonstrate classic severe combined immunodeficiency (SCID) impacting both T and B lymphocytes. Patients who inherit at least one missense allele, encoding a hypomorphic form of the RAG protein that generates greater than 1% enzymatic activity, have a more complex phenotype referred to as Omenn syndrome (38,39). Omenn syndrome is associated with immunodeficiency characterized by oligoclonal activated T cells and absent B cells. Classic Omenn syndrome includes erythroderma, lymphadenopathy, splenomegaly, granuloma formation in multiple organs, and infectious complications (38). Thus, genetic testing and identification of the specific mutation in the RAG genes is helpful in predicting the clinical course. The dysfunction of the immune system in the child (with either SCID or Omenn syndrome) can lead to engraftment of maternal T cells in the fetus, referred to as maternofetal transfusion, that may persist after birth (39). These maternal T cells perpetuate clinical problems in the child that are similar to graft versus host disease in patients undergoing bone marrow transplant.

Radiation-sensitive SCID (RS-SCID) results from inheritance of mutations in the *DCLRE1C* gene which encodes the Artemis protein (40). Artemis contains both endonuclease and exonuclease biochemical activities and is required for cleavage of the hairpin junctions specifically formed during VDJ recombination (41). As exemplified by the name of the disorder, patients with RS-SCID show a combined phenotype of significant radiation sensitivity and immunodeficiency, associated with accumulation of VDJ hairpin structures. Consistent with the concept that Artemis protein has a unique biochemical function in VDJ recombination, the gene is not essential and patients with RS-SCID demonstrate a variety of null and hypomorphic alleles (40). Patients with two null alleles do not demonstrate growth or developmental defects. A founder nonsense mutation in exon 8 of *DCLRE1C*, which results in nonsense-mediated decay of the *DCLRE1C* mRNA, is found in patients with RS-SCID from the Athabaskan Native American population (42).

Children with mutations in the gene that encodes DNA ligase IV (utilized during non-homologous end joining (NHEJ)) demonstrate microcephaly, immunodeficiency, and increased risk of lymphoma/leukemia (40). The *LIGIV* gene is essential, and patients with *LIGIV* deficiency carry a variety of hypomorphic alleles. *LIGIV* protein contains a BRCT motif, which is shared by other DSBR proteins including *BRCA1* (43). The clinical phenotype is also variable, with some patients demonstrating few of the features noted above and others having dysmorphic features accompanied by significant enough bone marrow failure to justify bone marrow transplantation (37,40). Cells from these patients demonstrate normal DNA damage checkpoint signaling and lack the ionizing radiation sensitivity seen in patients with AT.

AT-like disorder (ATLD) and Nijmegen breakage syndrome (NBS) are two disorders that result from mutations in genes encoding subunits of the MRN (*MRE11*, *RAD50*, *NBN*) heterotrimeric complex central to NHEJ repair (44,45). ATLD is a very rare disorder that results from biallelic mutations in *MRE11*. NBS results from biallelic mutations in the *NBN* gene, which encodes nibrin. The MRN complex comes to DSB independent of ATM activity. ATM then phosphorylates components of MRN as part of a complex DSBR signaling pathway (36,46). Despite the fact that *MRE11* and *NBN* function in the same complex, and cell lines derived from these patients demonstrate similar cellular defects, there are very distinct differences in their clinical phenotypes (44). Patients with ATLD demonstrate a similar neurodegeneration phenotype to patients with AT although with somewhat later age of onset. They lack the telangiectasia, elevated AFP, or reduction in immunoglobulins seen in patients with AT. To date, no patient with ATLD has been reported to develop leukemia or lymphoma; however, this is based on descriptions of less than 10 patients, so the cancer susceptibility is not well documented. NBS is quite distinct clinically from either AT or ATLD. Patients demonstrate microcephaly, developmental delay, dysmorphic features, reduced levels of immunoglobulins, radiation sensitivity, and increased risk of lymphoma (47).

The *ATR* (ataxia-telangiectasia and Rad3-related protein) gene encodes a protein highly related to *ATM*, which also encodes a member of the PI3 kinase family and targets many of the same proteins for phosphorylation when *ATR* is activated (34). Although it does not directly function in the double strand break repair pathway, the biochemical similarities justify inclusion in this section of the chapter. There are significant differences in the physiological impact of mutations in these two related genes. First, *ATM* is a non-essential gene, patients often inherit two truncating or null alleles, and there are no obvious growth defects or cognitive delays at birth. *ATR* encodes an essential function and thus patients with the *ATR*-related disorder Seckel syndrome are found to carry hypomorphic alleles of the *ATR* gene (40). *ATR* protein plays a crucial role in the response of

**TABLE 42-3 Disorders of Double Strand Break Response and Repair**

Condition	Gene/Protein	Clinical Features
Ataxia-telangiectasia (AT)	<i>ATM/ATM</i>	Cerebella ataxia, telangiectasia, immunodeficiency, leukemias, lymphomas and solid tumors
Ataxia-telangiectasia-like disorder (ATLD)	<i>MRE11/MRE11</i>	Neurologic features similar to AT with later age of onset, no telangiectasia, unclear cancer risk
Nijmegen breakage syndrome	<i>NBN/Nibrin</i>	Microcephaly, dysmorphic features, immunodeficiency, developmental delay and lymphoma risk
Radiation-sensitive–severe combined immunodeficiency disorder (RS-SCID)	<i>DCLRE1C/Artemis</i>	Sensitivity to ionizing radiation with severe immunodeficiency
Ligase IV deficiency	<i>LIGIV/ligase IV</i>	Microcephaly, immunodeficiency, anemia, developmental delay, lymphomas
SCID and Omenn Syndrome	<i>RAG1</i> and <i>RAG2/RAG1</i> and <i>RAG2</i>	Varying phenotype from isolated SCID to erythroderma, granulomas, lymphadenopathy and splenomegaly depending on mutation type. Can be complicated by persistent maternal T cells

cells to the single stranded DNA that is generated upon replication fork stalling, which occurs frequently even in the absence of exogenous damage. ATR also plays a role in repairing templates that contain bulky adducts. Thus, children with inherited deficiency in ATR function show severe growth defects with intrauterine growth retardation, small stature, and marked microcephaly (40). Patients also have very significant cognitive deficits and characteristic facial features. Consistent with the lack of a defect in response to double strand breaks, patients with Seckel syndrome and *ATR* mutations do not demonstrate significant ionizing radiation sensitivity or cancer predisposition. A mouse model of Seckel syndrome has been engineered by creating a murine line that has portions of the human *ATR* gene with an exon-skipping mutation swapped in the murine *Atr* locus. This mouse model recapitulates many of the features of Seckel syndrome, including microcephaly, and also demonstrates accelerated aging (48).

More recently, the use of homozygosity mapping and exome sequencing revealed mutations in two new genes, *CEP152* and *PCNT*, underlying some cases of Seckel syndrome. *PCNT* encodes pericentrin and is not essential. Patients with Seckel syndrome are often homozygous for a truncating allele (49). The proteins encoded by these two genes, CEP152 and pericentrin, respectively, bind each other and function in regulation of the centrosome. Absence of CEP152 function results in fragmented centrosomes, aneuploidy, and abnormal mitoses (50). The replicative stress evident in both ATR and CEP152/pericentrin deficient cells is thought to explain the similar clinical Seckel syndrome phenotype (49).

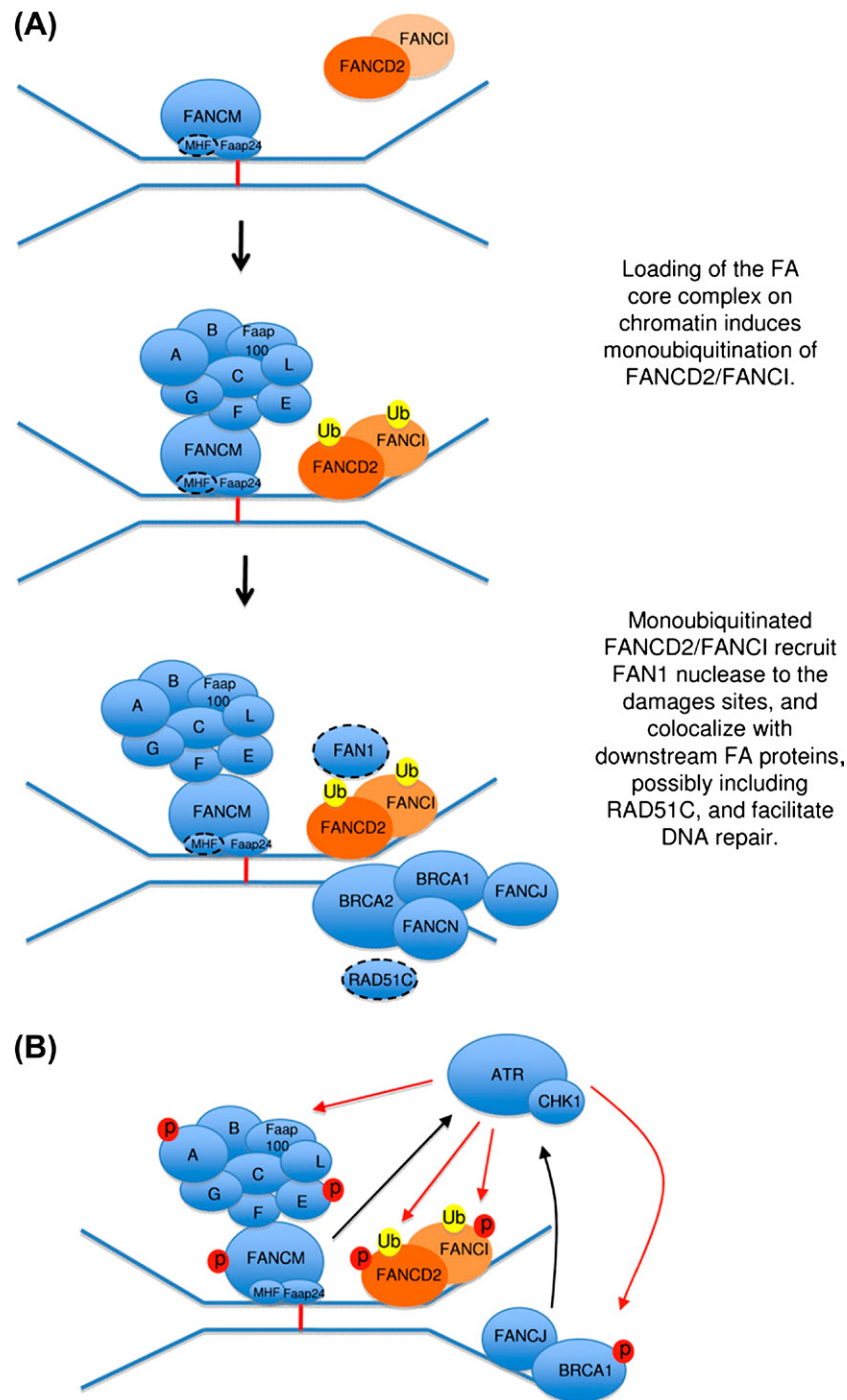

## 42.6 CROSSLINK REPAIR AND HOMOLOGOUS RECOMBINATION DEFECTS: BREAST-OVARIAN CANCER AND FANCONI ANEMIA

Extensive research on the genetic basis of hereditary breast and ovarian cancer was performed in the 1980s

and 1990s. This work led to the identification of the *BRCA1* and *BRCA2* cancer-susceptibility genes as discussed in Chapter 89 and reviewed by Narod and Foulkes (51). Analysis of hundreds of individuals heterozygous for *BRCA2* mutations has revealed that, in addition to breast and ovarian cancer risk, there is a lower but still statistically significant increased risk of prostate, pancreatic, stomach, and gallbladder and bile duct cancers, and malignant melanoma compared with the general population (51,52). The relationship with Fanconi anemia was not expected, as there is no evidence for a statistically significant increase in hematopoietic cancers in individuals heterozygous for *BRCA2* mutations (52). Both *BRCA1* and *BRCA2* encode proteins which act through large protein complexes to respond to double strand DNA breaks and mediate homologous recombination (Figure 42-5). As for other tumor suppressor genes that play a role in DNA repair, the tumor tissue from *BRCA1* and *BRCA2* heterozygous mutation carriers demonstrates inactivation of the second allele, typically associated with loss-of-heterozygosity events, resulting in localized DNA repair deficiency, very significant genomic instability, and aneuploidy (51,52).

The *Brca2* gene is essential for viability, based on studies of mouse models containing null mutations (53). Starting with the observation that cells from *Brca2* mutant mice demonstrated increased sensitivity to cross-linking agents, Howlett et al. reported the startling finding that rare forms of Fanconi anemia (FA subtype D1) resulted from biallelic inheritance of *BRCA2* mutations, often with one mutation being a null allele and the second a hypomorphic allele (54,55). This finding has led to an explosion of research documenting the complex overlap between interstrand cross-link repair (hallmark of Fanconi phenotype) and homologous-recombination-mediated repair (*BRCA1*, *BRCA2*, and associated proteins) including the discovery of many new Fanconi genes for the rarer complementation groups, which encode proteins that provide functions required in the

**FIGURE 42-5** A schematic model for the FA pathway. (A) Activation of the FA pathway. DNA interstrand crosslinks (ICL) is directly recognized by FANCM–FAAP24–MHF protein complex. This complex recruits the FA core complex by direct interaction between FANCM and FANCF. The recruited FA core complex, containing a PHD E3 ubiquitin ligase domain in the FANCL subunit, subsequently monoubiquitinates its two substrates, FANCD2 and FANCI, on chromatin. The monoubiquitinated FANCD2–FANCI becomes an active form, recruits newly identified nuclease FAN1 or interacts with a series of DNA repair proteins (including BRCA1, PALB2 ½FANCL, BRCA2, and FANCI, BACH1/BRIP1) at the damaged sites, and facilitates downstream repair pathways. RAD51C, a newly identified FA-like protein, may have a functional interaction with FANCD2 at this step. FANCD2–FANCI probably also recruits other nucleases and TLS polymerases to process the ICL (not shown). The new players in the FA pathway described in the text are highlighted in dashed lines. (B) The FA pathway cross-talks with ATR–CHK1 checkpoint proteins. ATR and its effector kinase, CHK1, are required for damage-inducible activation of the FA pathway. ATR–CHK1 phosphorylates (red arrows) multiple FA and FA-associated proteins, including FANCA, FANCE, FANCD2, FANCI, and BRCA1. FANCM is also phosphorylated upon DNA damage by an unknown kinase. In turn, the stability and activity of ATR–CHK1 are promoted (black arrows) by the FANCM–FAAP24 heterodimer and FANCI by independent mechanisms. FANCM also mediates the formation of the BRAF complex, which contains the FA core complex members and the BLM complex containing Topo IIIa and RMI1/2 (not shown). (With permission from Kee, Y.; D’Andrea, A. D. *Expanded Roles of the Fanconi Anemia Pathway in Preserving Genomic Stability*, Genes Dev. 2010, 24, 1680–1694.)

**FIGURE 42-6** Karyotypes of diepoxybutane-treated peripheral blood samples from a patient with Fanconi anemia. Abnormal structures that are increased in FA patients include quadri-radial (arrows—left panel) and tri-radial (arrows—right panel) formations. overlap between the cross-link repair and homologous-recombination-mediated repair (56).

Fanconi anemia is an autosomal recessive condition (except for the X-linked FA-B group) associated with bone marrow failure, congenital anomalies, and a substantially increased risk of malignancy in children and young adults (57–60). The most common cancers include acute myelogenous leukemia in children and head and neck cancers and genitourinary cancers in young adults. The cellular phenotype of Fanconi cells includes a profound sensitivity to cross-linking agents such as diepoxybutane (DEB) and mitomycin C (59). Treatment of the bone marrow failure requires bone marrow transplantation, and this sensitivity to DNA-damaging agents requires the use of specialized conditioning regimens to prepare the patient for transplant.

In addition to increased cell death, there are a variety of cytogenetic abnormalities, which are the basis of the diepoxybutane breakage assay (Figure 42-6). Increased breakage in response to these agents is used as the diagnostic test for FA (61). Patients with FA may demonstrate normal DEB breakage analysis from a blood specimen secondary to *in vivo* complementation where recombination between the two mutant alleles results in lymphoid cells that have corrected their repair defect; this circumstance may necessitate use of fibroblast analysis for a clear diagnosis (62). The DEB assay is also used for complementation analysis, which, as described for XP, allows us to distinguish FA patients from among the 15 different complementation groups (corresponding to 15 different FANC genes). Complementation for FA can be performed by fusion of patient cells with cell lines of specified complementation group or by transduction of retroviruses that express wild-type FANC proteins (63). For example, if DEB breakage is normalized by the transduction with a FANCA-encoding retrovirus, then the patient is considered to have FA-A.

Dozens of biochemical and molecular studies combined with complementation analysis have demonstrated that the FANC proteins function in DNA repair through participation in a number of different complexes (see Figure

42-5) (60,64). FANCA, C, B, E, F, G, and L proteins make up the FA core complex, which is thought to function in the first portion of the FA pathway. Over 90% of FA patients carry mutations in one of the core genes, with FANCA, FANCC, and FANCG being the most common. Individuals who fall within the FA core complex complementation groups have the typical combined phenotype of congenital anomalies, short stature, bone marrow failure (onset at average age of 6–8 years), and increased risk of leukemias and genitourinary and head and neck cancers. When activated by DNA damage or replication fork stalling, the FA complex proteins result in monoubiquitination of two proteins, FANCD2 and FANCI, which together form a heterodimer. There is little to no increased cancer risk seen among heterozygous carriers of mutations in genes that encode FA complex proteins (58).

An additional upstream component is FANCM, which is found complexed with FAAP24. The identification of FANCM as a verified FA protein is unclear, as the original FA-M patient cell line was subsequently reported to also contain a mutation in the FANCA gene and no other biallelic FANCM mutant line has been identified (65). At a biochemical level, FANCM also acts differently from other FA complex proteins as it binds directly to DSBs and appears to be required for bringing the FA core complex to the site of the break (66). FANCM:FAAP24 binds directly to the ATR checkpoint kinase. FANCM-deficient cells have a broader spectrum of sensitivity to exogenous agents, including hydroxyurea and camptothecin, compared with other FA cell lines, and the complex plays a bridging role between the FA pathway and a number of other DNA repair and checkpoint pathways.

The presence of FANCD2 monoubiquitinated and non-ubiquitinated species can be detected by Western blot analysis, and this assay is used by some laboratories as a diagnostic test (59). In particular, if protein lysates from a patient with FA demonstrate loss of the normal FANCD2 monoubiquitination, when further accentuated by exposure to cross-linking agents, this provides strong evidence that the patient carries mutations in one of the genes encoding the core complex. In normal cells, once FANCD2 and FANCI are monoubiquitinated, this sends a signal which is transduced to the DNA repair complexes that include FANCD1/BRCA2, FANCI/BRIP1, FANCA-N/PALB2, and FANCP/RAD51C (60,67). These latter proteins play a direct role in repair pathways that utilize homologous recombination (68).

Patients in the FA-D1 complementation group, due to biallelic deleterious mutations in BRCA2, have a particularly severe cancer phenotype with the vast majority being diagnosed with malignancies by the age of 5 years (69). Overall, patients with two deleterious BRCA2 alleles appear to have an increased incidence of congenital anomalies as well as multiple malignancies, compared with patients with one null allele and one missense mutation (55). Childhood onset of solid tumors is also more frequent in the FA-D1 patients

TABLE 42-4 RECQ Helicase Disorders

Disease	Gene/Location	Cellular Phenotype and Proposed RECQ Function	Cancer Predisposition
Bloom syndrome	<i>BLM</i> /15q26.1	Increased sister chromatid exchange Repair of stalled replication forks	Leukemia/lymphoma and solid tumors
Werner syndrome	<i>WRN</i> /8p11	Premature senescence Maintenance of telomeres	Soft tissue sarcomas and skin cancers
Rothmund–Thomson syndrome	<i>RECQL4</i> /8q24.3 <sup>a</sup>	Minor excess cytotoxicity to S phase agents Replication initiation	Osteosarcoma and skin cancers

<sup>a</sup>Only approximately 60% of patients with Rothmund–Thomson syndrome carry mutations in the *RECQL4* gene. The risk of osteosarcoma is associated with positive *RECQL4* mutation status (95).

compared with patients with mutations in the core complex genes, with almost half of this cohort having solid or brain tumor diagnoses including medulloblastoma, glioblastoma, and Wilms tumor (55). Thus, many different tissue types are susceptible to cancer when there is constitutional *BRCA2* deficiency. This same paradigm has been found regarding mutations in the gene encoding the *BRCA2*-associated protein *PALB2* (70). Children carrying biallelic *PALB2* mutations, or FA-N complementation group, also demonstrate a severe FA phenotype similar to FA-D1 (71,72). In seven FA-N families, there were five cases of medulloblastoma, three of Wilms tumor, two additional cases of AML, and one case of neuroblastoma, all diagnosed by 4 years of age (72). In contrast, analyses of families with heterozygous carriers of *PALB2* mutations demonstrated a two- to fourfold relative risk of breast cancer and increased risk of pancreatic cancer compared with the general population (73,74). Thus, the relative risk of breast cancer in *PALB2* mutation carriers is less than that described for heterozygous carriers of *BRCA2* mutations.

The Fanconi subtypes FA-J and FA-I are due to mutations in the repair genes *BRIP1/FANCI* and *KIAA1794/FANCI* (75,76). Carriers of heterozygous *BRIP1/FANCI* mutations have a twofold increase in breast cancer risk (77). However, the cancer phenotype in biallelic cases has not been well described due to the very small number of FA-J patients, but includes at least one child with chronic myelomonocytic leukemia (78,79). The *BRIP1/FANCI* protein is a structure-specific helicase which appears to be important for unwinding G tracts that can form guanine quadruplex DNA structures (80). An example of overlap in functions between proteins encoded by distinct disease genes is the recent finding that *FANCI* helicase and *BLM* helicase (described in section 42.7) interact physically in foci after DNA damage (68). Degradation of *BLM* helicase occurs when *FANCI* protein is absent.

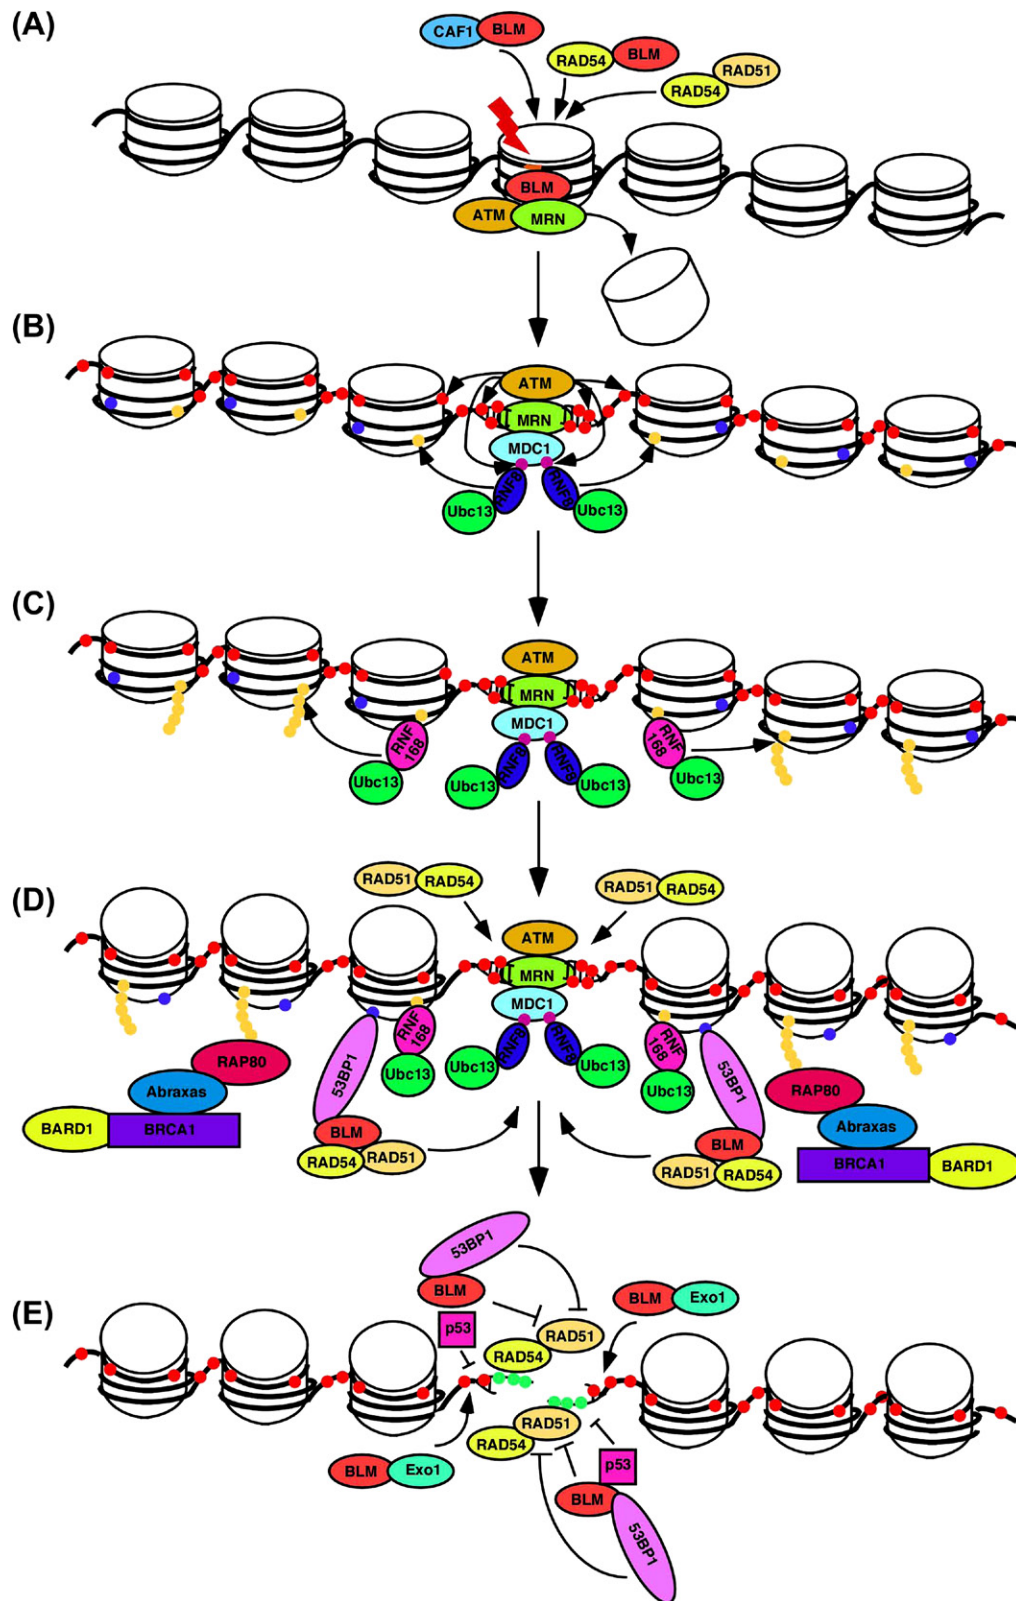

The most recently discovered Fanconi gene, *FANCP*, encodes the *RAD51C* homologous recombination protein (81). Again, biallelic carriers have Fanconi anemia FA-P, with significant childhood and young-adult cancer risk (82). In comparison to *PALB2* and *BRIP1*, heterozygous *RAD51C/FANCP* carriers have a breast and ovarian cancer risk close to that of *BRCA2* heterozygous

carriers (83). Thus, these distal members of the FA pathway play an important role in DNA repair that is mediated through homologous recombination. Mutations in these genes result in increased cancer risk in adult heterozygous carriers and a higher risk of solid tumors in children who are biallelic mutation carriers.

## 42.7 DISORDERS ASSOCIATED WITH RECQ HELICASE DEFICIENCY: BLOOM, WERNER, AND ROTHMUND–THOMSON SYNDROMES

There are three autosomal recessive disorders that demonstrate distinct clinical features but share predisposition to malignancy and are the result of mutations in the same family of helicases (Table 42-4). The three disorders, Bloom, Werner, and Rothmund–Thomson syndromes, are grouped together because they all result from biallelic mutations in members of the RECQ helicase family: *BLM*, *WRN*, and *RECQL4*, respectively (84). Extensive molecular biology and biochemical analyses demonstrate that these RECQ helicases play distinct roles in DNA metabolism.

Children with Bloom syndrome are very small at birth and have very significant lifelong short stature; a photosensitive rash, particularly prominent on the face; immunodeficiency; and predisposition to a variety of malignancies including leukemias/lymphomas and solid tumors (85,86). Similar to FA, the primary diagnostic test is a cytogenetic assay that monitors an increased number of sister chromatid exchange (SCE) events as the result of the hyper-recombination phenotype that results from loss of *BLM* activity. The cellular functions of the *BLM* helicase have been extensively studied and demonstrate an important role in resolving stalled replication forks and modulating recombination between sister chromatids (87). *BLM* helicase is a crucial component of homologous recombination and interacts directly with many of the other proteins described in the homologous recombination discussion (Section 42.6), such as *BRCA1* (Figure 42-7) (88). This high recombination rate is clinically evident in patients who are compound heterozygous for *BLM* mutations. In their lymphocytes, recombination between the two disease alleles can result in a corrected allele that expresses functional *BLM* protein (89). These

**FIGURE 42-7** Proposed model for the functions of BLM helicase during DNA damage response. (A) DNA double strand breaks (DSBs; red line) are recognized after BLM and/or RAD51-stimulated RAD54-dependent chromatin remodeling. BLM affects chromatin organization by interacting with and regulating the function of CAF-1. On remodeled chromatin, BLM accumulates and helps in the optimal ATM activation and MRN complex accumulation. (B) MRN complex promotes H2AX phosphorylation (γH2AX, red dots) which recruits MDC1. MRN complex, stabilized on the DNA lesion by MDC1, promotes further accumulation of activated ATM. ATM phosphorylates MDC1 (purple dots), promoting the binding and recruitment of RNF8/Ubc13 complex, which catalyzes the Lys63-linked ubiquitination of H2A and H2AX (yellow dots), causing a more accessible conformation of the chromatin. (C) RNF8/Ubc13-ubiquitinated histones recruit RNF168. RNF168/Ubc13 attaches K63-linked polyubiquitin moieties to RNF8-ubiquitylated histones (yellow dots). (D) Polyubiquitinated histones recruit RAP80, which helps in the accumulation of Abraxas/BRCA1/BARD1 at DSBs. Constitutive methylation of histones H3 and H4 (blue dots) are probably exposed due to RNF168/Ubc13-dependent ubiquitination. This results in the efficient recruitment of 53BP1 to the site of DNA damage. BLM again accumulates on the lesion in a 53BP1-dependent manner. Pro-recombinogenic proteins RAD51 and RAD54 interact with BLM, and accumulate at DSBs. (E) BLM functionally interacts with its partners, like RAD51, RAD54, 53BP1, and p53, during homologous recombination. RAD51 binds to the single stranded DNA by displacing replication protein A (green dots). While BLM, 53BP1, and p53 have anti-recombinogenic property, BLM also has a pro-recombinogenic resection function in coordination with Exo1. (From Tikoo, S.; Sengupta, S. *Time to Bloom*. Genome Integrity 2010, 1, 14.)

**FIGURE 42-8** Clinical features of Rothmund-Thomson syndrome (RTS). Shown are the hands of an adult with RTS who carries two deleterious mutations in the *RECQL4* gene, demonstrating the typical poikilodermatous rash, which often begins on the cheeks and spreads to the extremities, remaining lifelong. The absent thumb of the right hand is an example of the radial ray abnormalities seen in RTS patients with *RECQL4* mutations. (Photograph courtesy of L. L. Wang, MD—Baylor College of Medicine/Texas Children's Hospital.)

lymphocytes are visible due to the paucity of SCE events compared with the uncorrected cells.

Werner syndrome is characterized by premature aging (including early-onset atherosclerosis, diabetes, and cataracts beginning in the second decade) with increased incidence of soft tissue sarcomas (90). The premature aging is manifested at a cellular level as early senescence in fibroblasts from these patients. The WRN helicase encodes both a RECQ helicase module and 3'–5' nuclease activity (91). The aging phenotype demonstrated by Werner syndrome patients has resulted in extensive research into the role of the WRN helicase in maintenance of telomere integrity, despite the fact that WRN is not a subunit of telomerase itself (84). Current data suggests that WRN plays a role in the replication of the telomeric lagging strand, specifically in preventing telomere sister chromatid exchanges, which are associated with cellular senescence (92,93). Thus, BLM and WRN proteins decrease the number of exchanges, but in different chromosomal locations.

The third disorder in this group, Rothmund-Thomson syndrome (RTS), is characterized by a rash termed poikiloderma, which begins in infancy; skeletal dysplasias, including radial ray abnormalities; and cataracts (Figure 42-8). Children with RTS have a distinct predisposition to the development of osteosarcoma, and less frequently, skin cancers (94,95). Unlike other helicase disorders, there is not a clear cellular phenotype that can be used as a diagnostic test. RTS patients with osteosarcoma show little evidence for excess toxicity after chemotherapy treatment (96). Similarly, cells from RTS patients demonstrate only minor in vitro toxicity response to chemotherapy (97). In comparison, studies of the *RECQL4* helicase across species demonstrate that these helicases appear to have two fundamental roles in the initiation of DNA replication: (1) an essential function carried out by an N-terminal region of *RECQL4* that is homologous to the SLD2 family of proteins, and (2) functions associated with the intrinsic helicase domain (98). RAPADILLINO syndrome is a related autosomal recessive disorder, associated with individuals who carry at least one copy of a specific *RECQL4* founder mutation, which generates an abnormally spliced message with skipping of exon 7 (99). This abnormal *RECQL4* protein is mislocalized. Individuals with RAPADILLINO syndrome have an overlapping set of congenital anomalies with RTS, as well as an increased risk of lymphoma (100).

## 42.8 GENE-ENVIRONMENT INTERACTIONS: GORLIN-GOLTZ SYNDROME

Gorlin-Goltz syndrome, or nevus basal cell carcinoma syndrome (NBCCS), is an autosomal dominant disorder with many different features, including odontogenic jaw cysts, bifid ribs, palmar and plantar pits, frontal and biparietal bossing, calcification of the falx cerebri, and short fourth metacarpal bones (reviewed by Gorlin (101)). Heterozygous mutations in the *PTCH* gene, which encodes a homolog of the *Drosophila melanogaster* segment polarity gene, is the molecular basis for Gorlin-Goltz

syndrome (102,103). For this reason, NBCCS is not normally described in a chapter on DNA repair disorders but it highlights the gene–environment interaction that impacts cancer risk in a number of inherited disorders. The basal cell carcinomas (BCCs) are often first diagnosed in puberty. Adults with NBCCS may have hundreds of individual lesions. Exposure to both ultraviolet light and ionizing radiation can impact the number of BCCs that develop. For example, individuals of African-American descent have a later age of first diagnosis of NBCCS and an overall decreased number of BCC lesions compared with Caucasian populations, presumably due to the protective effect with regard to ultraviolet light exposure of increased melanin in the skin (104). In addition to BCC, there is a significant risk of medulloblastoma in childhood. Standard of care for treatment of medulloblastoma is radiation therapy to the corticospinal axis. Unfortunately, exposure of the skin to ionizing radiation (IR) can result in the development of hundreds of BCCs in the skin overlying the treatment field (104). These tumors develop with a latency of 5 years after radiation treatment, and therefore may appear at a much younger age than in patients with NBCCS who have not undergone radiation treatment. There is no evidence that the heterozygous constitutional cells have excess cytotoxicity in response to UV or IR. It is more likely that the exogenous exposure to radiation results in multiple forms of DNA damage, thus increasing the likelihood of a second hit in the wild-type *PTCH* locus facultative for tumorigenesis.

### Biography

**Sharon E Plon, MD, PhD, FACMG**, oversees the Cancer Genetics Program in the Texas Children’s Cancer Center as well as being chief of Baylor Cancer Genetics Clinics. She is a graduate of MIT in chemistry and chemical engineering and is a graduate of the Medical Scientist Training MD–PhD Program at Harvard University. Dr Plon completed her medical genetics fellowship at the University of Washington prior to being recruited to Baylor College of Medicine in 1993. She is currently a professor in the departments of Pediatrics and Molecular and Human Genetics and a member of the Human Genome Sequencing Center. Her laboratory now focuses on the identification of human genes that impact genetic susceptibility to developing childhood cancer, including two recently funded projects to perform massively parallel next-generation sequencing of whole exomes and genomes in families with unusual patterns of childhood cancer.

## Autosomal Trisomies

*Cynthia J Curry*

USCF Genetic Medicine Central California, Fresno, CA, USA

This article is a revision of the previous edition article by John L Tolmie and Una MacFadyen, volume 2, pp 1011–1037, © 2007, Elsevier Ltd.

### 43.1 INTRODUCTION

It is now over 50 years since the recognition of the chromosomal basis for trisomy 21 (T21), Down syndrome (DS), first described clinically by the British physician John Langdon Down in the nineteenth century. Recognition of the other two major trisomies, trisomy 13 (T13) and trisomy 18 (T18), followed quickly after the discovery of T21 (1). Calculated live-birth rates of these conditions are 1 in 629 for T21, 1 in 6666 for T18, and 1 in 12,500 for T13 (2,3). The rates of all three autosomal trisomies increase markedly with advancing maternal age (4,5,6) and are lower than the rates observed in prenatal life since only about 25% of T21 conceptions, 5% of T18 conceptions, and 2.5% of T13 conceptions survive to birth, with most but not all intrauterine deaths occurring in early pregnancy.

Postnatal mortality associated with T18 and T13 is also very high, and the median survival time of infants with these trisomies is about 10 days. About 5–10% of T18 and T13 infants survive to 1 year of age (7,8,9). These survival figures have not changed in recent years, whereas T21 survival data indicate greatly improved life expectancy. This is due primarily to the longer survival of infants with heart disease—over 80% survival in many centers (10,11). Survival has also increased because of treatment of infections with antibiotics and generally enhanced surveillance for the medical complications of DS. This improved life expectancy has implications for health care provision for older individuals with DS (12,13) as well as informing decisions regarding health maintenance and intervention in the infant and child (14,15). In developed societies, increasing life expectancy has been accompanied by a decreasing birth prevalence of DS because of prenatal screening programs that offer invasive and noninvasive prenatal diagnosis (3,16,17,18).

### 43.2 GENETIC COUNSELING IN THE TRISOMIES

The diagnosis of an autosomal trisomy carries with it general issues, applicable in many cases, and specific or unique

issues in each individual case. From the geneticist and genetic counselor's perspective, there is no single approach that is suitable for all who are affected by a trisomy. The diagnosis of the affected fetus or infant is a fact that is usually conveyed under difficult psychological circumstances. Parents need to be treated with respect and with cultural sensitivity. Certainly the approach is different in the prenatal setting versus the neonatal setting (19,20).

Parents should be intimately involved in all aspects of this communication process and have consistently reported that the words used when they are first informed have a permanent effect on their later adjustments to their new situation, their feelings about their child, and their relationships with health professionals (21). In general, since we can now anticipate a long lifespan for the child with DS, optimism and encouragement seem warranted and should be conveyed, especially when counseling the family of a newborn (21,22).

Very early involvement of the clinical geneticist and counselor are essential in the prenatal and postnatal management of trisomies 13 and 18. It is critical to assess the family unit in making management decisions and to involve the parents fully. Variables such as family and financial resources, impact on siblings, and likely burdens of care need to be compassionately explored in making these decisions (23). Prenatal diagnosis by amniocentesis or chorionic villus biopsy (and occasionally ultrasound only) can help a family reach appropriate decisions about continuation of the pregnancy and management of labor and delivery, as well as decisions with respect to the health care of their affected child. In trisomies 18 and 13, counseling should emphasize a realistic appraisal of their child's prognosis, with an emphasis on support and comfort care. In these two trisomies, heroic measures such as intubation and cardiac surgery are usually not indicated because of the early lethality of these conditions (8). Nonetheless, some families will request intensive support of their newborn, and these decisions need to be respectfully discussed by the health care team and the family. Ongoing grief support is valuable and

should be offered to these families who may suffer for months or years after the loss of an affected child.

The Internet offers increasing accessibility of information and support for families and many of these sites offer easy connections to locally available services. Families with access to the Internet should be supported in their efforts to seek outside information and geneticists and counselors should act as facilitators in directing families to reputable sites. Sites such as those recommended by the Medical Library Association or organizations such as the National Institutes of Health are reputable. A consumer and patient health information section of the Medical Library Association has a link that lists “General Health Websites You Can Trust.” A list of the top 100 can be found at <http://caphis.mlanet.org/consumer>.

Many communities have excellent local resources and support groups for parents of children with DS and the National Down Syndrome Society also offers extensive information for families (<http://www.ndss.org>). The “Beyond the Basics” patient information library is open to all on the web and can be accessed through a patient information Website ([www.uptodate.com/patients](http://www.uptodate.com/patients)).

Families should be cautioned against sites offering unorthodox treatment protocols or hopes for “cures.” Families of affected children are uniquely vulnerable to claims of treatment success and often may spend substantial amounts of money in the pursuit of an improved developmental outcome. Counseling should address these alternative therapies and help direct families to legitimate sources of help.

The need for accurate information and authoritative and consistent support for parents of children with trisomies 18 and 13 has led to several organizations such as SOFT US (Support Organisation for Trisomies 18 and 13) and SOFT UK ([www.soft.org](http://www.soft.org)). These groups most often offer support and solace for those parents of affected babies surviving the immediate neonatal period; they also offer support for families whose children have died.

In advising families, general principles of counseling are always relevant. Many parents know of DS from personal experience and seek to understand the range of associations and the plans for specific investigation and management at an early stage. An initial offer of basic information leaflets with telephone or Internet contact details, as well as details of a local parent support service, is appropriate.

Genetic counseling may be offered to the family at one or several different stages: at the identification of risk, at confirmation of diagnosis, or at the time of another pregnancy for the parents or family planning for the unaffected siblings. Each family will have different expectations of counseling and vastly different reactions to the information it brings (21,24). The counselor who helps parents adjust to the diagnosis of an autosomal trisomy needs insight, intuition and compassion.

## 43.3 DOWN SYNDROME (TRISOMY 21)

### 43.3.1 Cytogenetic Diagnosis

In DS, no single clinical feature is pathognomonic, although the combination of facial dysmorphic features is highly specific (25). Chromosome analysis is necessary in each case to confirm the diagnosis and to assess genetic implications for the family (26).

In 95% of DS cases there is a complete extra chromosome 21. This is most often due to a nondisjunction event at the first meiotic division, and the chance of this occurring rises in older mothers. In 4% of DS cases, the extra chromosome 21 is translocated to or fused with another large or small acrocentric chromosome (#13, 14, and 15 are D-group acrocentrics; 21 and 22 are G-group acrocentrics). This fusion, sometimes described as a whole-arm exchange, is also called a Robertsonian translocation in recognition of the American cytogeneticist Robertson's contribution from his studies of chromosome fusion in insect cytogenetics early in the twentieth century. Usually, the Robertsonian chromosome is dicentric, although it may appear monocentric because of suppression of one centromere.

Nonhomologous (sometimes called heterologous) Robertsonian translocations comprise fusion of two different acrocentrics and are more frequent than homologous Robertsonian translocations. The prevalence of the balanced rob(14q21q) translocation is about 1 in 10,000, and the rob(21q21q) is about one-third as frequent. About a third of translocation DS cases are inherited from one parent, and usually it is the mother who is the balanced carrier. De novo rob(14q21q) DS also originates most often in maternal germ cells (27) and is due to a meiosis II nondisjunction event with an unusual pattern of genetic recombination in meiosis I preceding nondisjunction in meiosis II (28). Homologous Robertsonian translocations such as rob(21q21q) are mostly isochromosomes but can be true translocations if they are formed by fusion of maternal and paternal homologs postconception (29). Only about 7% of DS individuals with rob(21q21q) or rob(22q21q) have a carrier parent, and the mother is usually the carrier.

### 43.3.2 Trisomy 21 Mosaicism

In 1% of cases, T21 mosaicism is present (30). The first case reported in 1961 by Clarke and colleagues (31) was a 2-year-old girl who was selected for detailed cytogenetic study because she had physical features of DS but superior intellectual development. This girl had T21 in 13% of cells from blood leukocyte cultures and 34% of cells derived from fibroblast cultures; the remaining cells were 46,XX. There is a general tendency for the proportion of trisomic cells to be higher in fibroblasts and in early life, so the proportion of trisomic cells in one individual is not necessarily constant over time (32). In

general, in mosaic T21 the clinical signs of DS are less prominent (32,33). Patients with low-level mosaicism will likely be increasingly recognized with the utilization of microarray (34). A low level of mosaicism in an unaffected individual may not have immediate clinical significance, but the mosaic trisomy parent may be at high risk of offspring with full trisomy (35).

### 43.3.3 Prenatal Diagnosis

The incidence of DS increases in a nonlinear fashion and ranges from approximately 1/1500 in women from 15 to 25 years to 1/10 for a 48-year-old woman. The incidence remains constant between 15 and 25 and then rises slowly between 25 and 35, increasing by a factor of 4 from 35 to 40 and by a factor of 10 between 40 and 45. Initially all screening efforts in DS were directed at women at age 35 and older. This age was picked by consensus as the risk at that time was thought to approximately equal the procedure-related risks and to be cost effective (36,37).

In practice, the actual procedure-related risks are lower than originally thought. Some families place a high value on the definitive knowledge from a diagnostic test, even if there is risk, as they want the option of ending an affected pregnancy. Other families, especially those who have had prior unsuccessful or high-risk pregnancies, will choose serum screening tests and ultrasound to avoid the potential use of an invasive test (38). Based on these considerations, in 2007, the American College of Obstetrics and Gynecology recommended that all women be offered serum screening prior to 20 weeks gestation and that all women should have the option of definitive diagnostic testing regardless of maternal age (39).

### 43.3.4 First and Second Trimester Screening

Serum screening in the first trimester (11–13 weeks gestation) looks at two serum analytes, pregnancy-associated plasma protein A (PAPP-A) and human chorionic gonadotropin (hCG). The abnormal values in DS are observed

empirically and are incompletely understood. Altered placental function is an attractive hypothesis (40). Beta hCG performs best between 9 and 13 weeks of pregnancy and performance increases with increasing gestational age (41). In contrast to hCG, PAPP-A performance declines with increasing gestational age between 9 and 13 weeks (42,43).

At the same time or shortly before or after first-trimester serum screening there should be ultrasound determination of the nuchal translucency (NT). A small space in the posterior neck is a normal finding in all first-trimester fetuses, but enlargement of this space is associated with an increased risk of DS as well as other abnormalities such as Turner syndrome, Noonan syndrome, or congenital heart disease (44). An enlarged NT space is usually associated with distended jugular lymphatics, which are commonly found in a number of disorders. Even in an abnormal fetus the enlarged NT often resolves later in pregnancy. Risks associated with an increased NT should not be revised downwards even if the measurements revert to normal later in pregnancy (42). The optimal timing for the determination of NT is 11 weeks, but this can be performed between 10 and 14 weeks gestation. Early studies of NT revealed significant intraoperator variability and variability based on the quality of the ultrasound equipment. NT techniques have been clearly delineated and involve measuring the nuchal fluid space from inner to inner borders in a midsagittal plane (Figure 43-1). Distinguishing the amnion, which may not separate from the chorion until 16 weeks, is important, as the amnion can be confused with the posterior aspect of the fetal skin. Proper training and quality verification are now required elements in screening programs utilizing NT (44,45). NT in combination with serum screening can be used to determine those at very high risk for DS and early invasive testing by chorionic villus biopsy can be offered. In the State of California the prenatal screening program has determined that NT measurements equal to or over 3.5 mm constitute a risk for aneuploidy of greater than 1/5 and that all such mothers should be offered invasive diagnostic testing regardless of serum screening results. Several studies have examined

**FIGURE 43-1** Features of Down syndrome. (a) Brushfield spots. (b) Typical hand configuration with transverse crease and fifth finger clinodactyly. (c) “Sandal” gap—increased space between toes one and two (d) Typical ear, which is small (<3%) with overfolded helix.

the risks associated with enlarged NT. In general, the greater the enlargement the higher the risk for aneuploidy. Most fetuses with DS had NTs less than 4.5 mm, whereas fetuses with Turner syndrome and trisomies 18 and 13 had NTs in excess of 4.5 mm (46). The distinction between an enlarged NT and cystic hygroma is not entirely clear (47). In general, cystic hygromas tend to be larger and extend along the length of the fetus and are more often septated. Size, however, is the major determinant of outcome, probably not the distinction between cystic hygroma and isolated increased NT (48).

The optimal detection of DS involves testing in both the first and second trimester plus NT measurements. As discussed earlier, screening in the first trimester consists of two analytes: PAPP-A and beta hCG, plus NT. In the second trimester there are four analytes, which include alpha fetoprotein (AFP), unconjugated estriol (uE3), hCG and inhibin A, and these should be measured between 15 and 20 weeks gestation. When there is no local availability of NT measurement, a serum integrated test result can provide risk information, which has the highest detection rate without an NT measurement.

The FaSTER (First and Second Trimester Evaluation of Risk) trial looked at outcomes of pregnancy in 38,000 women followed in 15 centers in the United States who underwent first- and second-trimester serum screening plus or minus NT. At a detection rate of 85% there was a 4.8% false-positive rate for first trimester plus NT; a 4.4% false-positive rate for serum integrated, a 0.8% false-positive rate with fully integrated (plus NT) and a 7.3% false-positive rate for quadruple screening (43,49).

Many mothers do not enter prenatal care until the second trimester, and for such women the quadruple screening test (AFP, uE3, hCG and inhibin A) offers the best screening strategy. Preferably such testing is done in conjunction with an ultrasound scan for fetal anatomy. This can help refine risks, although ultrasound alone should generally not be used as a primary screening tool.

The pattern of analytes differs in fetuses affected with DS, T18, and Smith–Lemli–Opitz syndrome. In DS, the AFP and uE3 are depressed and hCG and inhibin are increased. In T18, AFP, uE3 and hCG are all low, whereas inhibin is unchanged. No risk information is obtained for T13. Risk calculations include adjustment for maternal weight, smoking, diabetes and multiple gestation.

### 43.3.5 Ultrasound Markers in Trisomies 21, 18 and 13

The prenatal detection of aneuploidy is a major goal of prenatal detection programs. Fetuses with T21 and T18 frequently have ultrasound evidence of congenital anomalies and, in addition, have what have been termed “soft markers,” which increase the risk for aneuploidy, but are also frequently seen in normal fetuses. These soft markers have no clinical sequelae by themselves and are usually fleeting, resolving by late gestation. The ultrasound

finding of an enlarged NT has been discussed. Other markers seen more frequently in aneuploidy include echogenic bowel, absent nasal bone, pyelectasis, mild shortening of the long bones, echogenic intracardiac focus and choroid plexus cysts. These findings can be seen in 11–17% of normal fetuses, but the presence of more than one marker increases the risk for aneuploidy (50). There has been significant controversy over the reporting of echogenic foci and choroid plexus cysts, as they are most often associated with a normal outcome and these findings provoke parental anxiety and may lead to invasive testing. Review of the evidence suggests that the finding of an isolated echogenic focus in the heart in an otherwise low-risk woman does not increase the risk for aneuploidy (51–53). Choroid plexus cysts are present in 30–50% of fetuses with T18 compared to 1–3% of all second-trimester fetuses; however, most large studies suggest that an isolated choroid plexus cyst in the presence of an otherwise normal fetal ultrasound is associated with a normal karyotype (54,55). Combining multiple markers, including serum screening, fetal NT and the presence or absence of the nasal bone increases DS detection. In one study, looking at these variables between 11 and 13 6/7 weeks in 20,000 pregnancies, 90% of DS was detected with a 2.5% false-positive rate (56).

In the second trimester, ultrasound may help refine the diagnosis of chromosomal aneuploidy. Over 1/3 of fetuses with T21 have structural malformations, including cardiac defects, central nervous system (CNS) anomalies (especially ventriculomegaly), anomalies of the gastrointestinal tract (especially duodenal atresia), and facial findings including brachycephaly, small ears, cystic hygroma and a thickened nuchal fold. A thickened nuchal fold is the most sensitive (40–50%) and specific (99%) single marker for DS detection in the second trimester (57). Soft markers such as mild long bone shortening, fifth finger clinodactyly, and sandal gap great toe should not be used as in isolation to detect DS in an otherwise low-risk pregnancy. Studies have suggested that one should not use second-trimester ultrasound alone to recommend an amniocentesis in women who have had normal serum screening. A study of 9000 women with abnormal serum screening and a normal ultrasound revealed a reduced risk of DS; however, in one study, about 45% of DS would have been missed in the presence of abnormal biochemical screening and normal ultrasounds in women declining amniocentesis. In addition, with normal serum screening results and an ultrasound with positive soft markers, 1200 amniocenteses would need to be performed to identify one fetus affected with T21 or T18 (58).

In T18, several second-trimester findings help identify affected fetuses. These include overlapping fingers, clubfeet, components of the Dandy Walker malformation, oral clefts, cardiac defects, micrognathia, omphalocele, diaphragmatic hernia, renal abnormalities and single umbilical artery. Intrauterine growth restriction and polyhydramnios are also common ultrasound findings in

T18. The detection rate for T18 is higher than 90% by combining ultrasound findings with abnormal first and/or second-trimester serum screening. Conversely, if the ultrasound is normal the risk of T18, even with abnormal serum screening, is low (59,60).

T13, the rarest of the autosomal trisomies, is associated with more severe structural abnormalities. Seventy five percent of T13 fetuses die in utero. Useful ultrasound findings include holoprosencephaly, midline facial abnormalities, polycystic kidneys, cardiac defects, neural tube defects, postaxial polydactyly, ventriculomegaly and posterior fossa abnormalities. Since some of these abnormalities can be visualized at 11–14 weeks gestation, first-trimester diagnostic rates are high (61).

An exciting development in the prenatal diagnosis of the major trisomies has been the analysis of cell-free nucleic acids in maternal blood. The presence of fetal material in the maternal circulation has been known for some time. Initially in the 1990s, the isolation of nucleated red blood cells along with fluorescence in situ hybridization (FISH) and polymerase chain reaction (PCR) allowed for detection of T21. The comparable effectiveness of ultrasound and serum screening and their lower costs kept this technology from acceptance in clinical practice, however. The knowledge that 3–6% of the cell-free nucleic acids in maternal plasma are fetal in origin along with technical advances, including digital PCR and massively parallel genomic sequencing, has led to some optimism that first-trimester noninvasive screening of maternal blood will soon allow for prenatal diagnosis of the trisomies as well as single gene disorders (62–64).

The postnatal confirmation of the diagnosis of T21 is critical to rule out a translocation or mosaicism and usually involves routine karyotyping. Recent efforts to reduce costs using new molecular techniques such as short tandem repeats for chromosome 21 are promising (65).

### 43.3.6 Clinical Diagnosis

DS is characterized by a recognizable pattern of dysmorphic features, congenital malformations and other

health conditions. In newborns, eight cardinal signs are redundant: neck skin, down turned mouth corners, hypotonia, flat face, small typical ears, epicanthal folds, “sandal gap” between first and second toes, and protruding tongue (66) (Figure 43-1). Clinical experience is an excellent predictor of DS, but the occasional infant will be atypical and cause even the most experienced clinician difficulty in diagnosis (25). Severe prematurity may also lead to a late diagnosis, as the findings may be subtle in this group. Ethnicity affects ease of diagnosis: In South Africa, delayed diagnosis was common in black neonates in whom facial features of DS were less readily recognized by the attending medical staff and by infants’ mothers (67,68).

In children under 2 years of age, 10 discriminating clinical signs of DS are brachycephaly, oblique palpebral fissures, nystagmus, flat nasal bridge or root, narrow palate, folded ear, short broad neck, incurved fifth finger, sandal gap between great toe and second toe, and hypotonia (Figure 43-2) (69). The adult with T21 has facial features that have changed with age (70) (Figure 43-2). The nasal root becomes more prominent, epicanthal folds become less prominent, and increased growth of the lower face occurs, just as it does in chromosomally normal individuals (Figures 43-3 and 43-4). Older literature photographs of adult individuals with T21 tend to reinforce old stereotypes, emphasizing features such as obesity, abnormal tongue fissuring and an open mouth.

### 43.3.7 Differential Diagnosis

In practice, one-third or more of requests for karyotyping to rule out DS give a normal result (25,71), but published clinical follow-up studies on the development of the infants who test negative are lacking. More rarely, features of the DS phenotype are present in cases with cryptic chromosome 21q imbalance (72) or undetected mosaicism for T21 (30). In newborns, Zellweger syndrome or tetrasomy 12p syndrome may be initially mistaken for T21. In older individuals, the facial appearance of Smith–Magenis syndrome can resemble DS. A “new”

**FIGURE 43-2** The changing face of Down syndrome with age. (a) infant, (b) young child, and (c) 47-year-old adult (note hearing aid, gray hair, edentulous).

**FIGURE 43-3** Transient myeloproliferative disease in a hydroptic newborn with Down syndrome.

chromosomal syndrome that has a close facial resemblance is the microdeletion of chromosome 9q34 (73).

### 43.3.8 Development, Personality, and Intellectual Disability

The stereotype of DS is a floppy, sociable, undemanding infant who turns into a placid, affectionate, good-natured, music-loving, moderately intellectually disabled adult. In fact, individuals with DS are just as different from each other as their chromosomally normal peers: some are happy and others are sad, some are flighty and impulsive and others are careful and steady. Just as in the general population, a minority of individuals exhibit deviant behaviors or suffer serious conditions such as autistic spectrum disorders (74). Overall, few individuals with DS have serious behavioral disturbances (75,76). There does appear to be a distinctive neurocognitive phenotype (77).

Many changes in the brain and behavior in DS are described (78,79), and correlation of structural CNS findings with cognitive abnormalities has been studied (80). Delayed myelination, reduction in growth of frontal lobes, narrowing of the superior temporal gyrus, and reduction in size of the brainstem and cerebellum are commonly reported neuropathologic changes in infancy. In older children, there is reduced brain volume, especially affecting the hippocampus, and, from mid-adult life onward, the predominant neuropathologies are changes similar to Alzheimer disease (see later). In one study, when followed over time there was a decrease in IQ, correlating somewhat with the age-related findings of early dementia and depression in DS adults (80).

Developmental delay becomes apparent during the first year of life, with motor skills being the most obviously affected milestones. The average age of sitting is 11 months; crawling 17 months; walking 26 months. Children with DS develop speech in the same order as

typical children, but the rate is slow, with the average time of first words at about 18 months (81–83). Parents should be encouraged that almost all DS individuals will learn to talk, although language is probably the most impaired area of functioning, hampering attempts to integrate individuals with DS into the community and their efforts to live independently. Abbeduto and colleagues (84) present an extensive review of language development in DS.

Virtually all children with DS have intellectual disability. Most are mildly to moderately impaired, with IQs in the 50–70 or 35–50 range. Some are severely impaired, with IQs of 20–35. The most common pattern of impairment is for receptive language to equal the mental age of the child, with expressive language being more delayed. Vocabulary continues to increase and surpass mental age in adolescence (85). Selective learning problems such as difficulty understanding sequences or rules of grammar have been described (86).

The histories of DS and Alzheimer dementia (AD) have been linked for a very long time. The characteristic brain findings of AD, including neuritic plaques, which are extracellular deposits of amyloid beta protein in the cerebral cortex and neurofibrillary tangles, are seen in DS as early as age 8 and precede the development of clinical dementia. It has previously been thought that nearly all individuals with DS have characteristic brain changes by 35–40 years, accompanied by clinical signs of AD, particularly with frontal lobe involvement. More recently, studies have suggested that the risks are slightly lower, with 50–70% of DS individuals having AD by age 60–70 (87). Along with the AD phenotype there is evidence of generalized accelerated aging, documented by age-related skin changes, osteoporosis, osteoarthritis, hypogonadism and cataracts (88).

### 43.3.9 Growth

At birth, infants with DS show mild growth retardation, with mean birth weight, length, and head circumference lying between the 10th and 15th percentiles calculated for chromosomally normal infants (89). In a study of 105 children with DS, length, weight and head circumference were below those of typical children and remained lower until puberty, with the growth spurt occurring earlier than in the normal population (11 in boys and 9.5 in girls) (90). Growth charts for children with DS are available in the United States and in several other countries (91–94). Successful efforts have also been reported to produce specific growth data for use in an electronic medical record (95).

Obesity is common in DS (96), and it is suggested that all those over 5 years with weight over 75th percentile should have the body mass index (BMI) charted. BMI above 98th percentile is an indication for further assessment. The majority of children with DS are obese by age three to four (82). The prevalence of obesity in DS

(BMI > 27.8/kg/m<sup>2</sup> in males and >27.3/kg/m<sup>2</sup> in adult females) is greater than in the general population (45 and 56%). Obese women with DS may have better verbal memory, with a suggestion that higher endogenous estrogen levels are contributory (97). Obesity in DS is not due simply to increased food intake with decreased energy expenditure. A systematic review of published literature failed to provide convincing evidence that increased aerobic exercise will improve physical or psychosocial outcomes (98). Intuitively, however, scheduled training sessions in the company of peers encourage friendship and social opportunities. Exercise also helps to combat low bone mass and osteoporosis, which are more prevalent in adults with DS (99,100).

Short stature is common in DS, especially in infancy and adolescence. Stature is most reduced in children with severe congenital heart disease (101). In addition, several medical conditions causing poor growth, such as celiac disease, are more common in DS. Medical and dietary assessments are indicated when growth measurements lie below the second percentile (102). The cause of most short stature in DS remains unclear. Low levels of IGF1 and decreased levels of growth hormone have been reported in some DS children (103).

Children with DS who are not growth hormone deficient do show a height response to growth hormone therapy (104,105), but such treatment is largely undertaken on a research basis and is still being assessed in the longer term. Blanket prescription of growth hormone is not recommended in the absence of proven growth hormone deficiency (105). Results from a study in Sweden did not demonstrate behavioral and cognitive improvements in treated young children (104). A study in 2010 (106) on early growth hormone treated children with DS revealed a greater head circumference in DS as well as improved performance on the Leiter and WISC III as compared to control DS children. Further studies are needed.

### 43.3.10 Congenital Heart Disease

Congenital heart defects (CHDs) are present in approximately 44% of individuals with DS and all newborn infants should undergo echocardiographic examination in the neonatal period. In the Atlanta Down Syndrome project, the breakdown of defects in the children with DS was as follows. Atrioventricular canal defect, comprising atrial septal defect with abnormality of the atrioventricular valves and ventricular septum, with or without other lesions, was seen in 45% of all CHD cases (107). In fetal life about 50% of fetuses with isolated canal defects have T21. Isolated ventricular septal defect with or without other lesions was seen in 35%, isolated secundum atrial septal defect in 8% and patent ductus arteriosus in 7%. Tetralogy of Fallot and other complex lesions made up the remaining 5%. In two studies of adults with DS, mitral valve prolapse was found in 46%, mitral regurgitation in 17% and aortic

regurgitation in about 7% of patients (108,109). This has implications, as such individuals should probably have prophylaxis for dental work to reduce the risk of bacterial endocarditis (110,111).

Medical and surgical treatments of heart defects in children with DS are similar to the treatments used in the care of chromosomally normal children, with modern postoperative morbidity and mortality rates similar in both groups (112,113); however, pulmonary hypertension is more common in DS (114,115). Postulated precipitating factors include anatomic variations such as maxillary hypoplasia and macroglossia, hypertrophy of the tonsils and adenoids, and sleep apnea with or without upper airway obstruction. Coronary artery disease, typically said to be rare in DS, may become more frequent as the population of older DS individuals increases (116).

### 43.3.11 Oral Health

Dental problems are common in DS. Malocclusion, tooth grinding, and tongue thrusting can impair chewing, while periodontal disease, akin to juvenile periodontitis, is especially common and may reflect an underlying immunologic predisposition. The tendency to poor oral health in DS children can be improved by regular dental care, at least as indicated by some studies (110,111,117). Despite the prevalence of the periodontal problems, caries may actually be less prevalent in DS individuals.

### 43.3.12 Gastrointestinal Complications

Gastrointestinal tract anomalies occur in about 5% of children with DS (118). Two major gastrointestinal anomalies associated with DS are duodenal atresia and Hirschsprung disease. About 2.5% of infants with DS have duodenal atresia or stenosis, sometimes in association with annular pancreas (86). About 20–30% of children with duodenal atresia have T21. Slightly less than 1% of patients with DS have Hirschsprung disease, which is higher than that in the general population (119). Two percent of patients with Hirschsprung disease have T21. A small number of T21 infants have both duodenal atresia and Hirschsprung disease, and in such cases dual pathology causes diagnostic problems because the presenting features of duodenal atresia overshadow signs of Hirschsprung disease. For these two major gastrointestinal anomalies, surgical outcome in the short term can be just as good as with chromosomally normal children, but presence of additional cardiovascular and respiratory malformations may lead to increase in delayed mortality (120–122).

Other congenital intestinal abnormalities that occur more frequently in T21 infants include tracheoesophageal (TE) fistula, imperforate anus, omphalocele, duodenal bands, annular pancreas, ileal and jejunal atresias, and microcolon (123). Esophageal motor disorders,

especially achalasia, are underdiagnosed complications of DS (124,125).

Even in the absence of Hirschprung disease, constipation is a common complaint in children with DS, and contributing factors are certainly hypotonia and relative inactivity. In the adult with DS chronic unexplained diarrhea may be seen in up to 20% of individuals. In addition, *Helicobacter pylori* infection has been found in as many as 66% of DS individuals (126).

Celiac disease has a biopsy-proven prevalence of between 5 and 16% in DS individuals. In order to avoid harmful consequences of undiagnosed and untreated celiac disease, serologic screening of children and adults using antiendomysial antibodies or tissue transglutaminase has been recommended, with biopsies for screen-positive cases (127,128). Positive cases should undergo small bowel biopsy. Negative cases should be rescreened at intervals or have human leukocyte antigen (HLA) typing that shows that they are not HLA DQ2 or DQ8 (129).

### 43.3.13 Otolaryngologic Problems

Ear, nose, and throat (ENT) complications cause much morbidity in DS, and upper airway problems can be life-threatening (130). Anatomic abnormalities affecting the external and internal ear contribute to the high prevalence of middle ear infection and hearing impairment. Hearing deficits occur in 38–78% of individuals with DS (131). The majority of DS children have a conductive hearing loss, 90% of which is caused by otitis media with effusion. Stenotic ear canals, impacted wax, ossicular chain, and cochlear malformations are also common. Ideally, all infants with DS should undergo newborn hearing screening and be followed by clinical examination, pure tone or behavioral audiometry, and tympanometry. It has been proposed that audiologic assessments with maximum frequency between 6 months and 1 year be performed, lessening in frequency thereafter and continuing into adulthood (132).

For infants with hearing impairment, there is a trend toward more aggressive treatment of conductive hearing loss and early amplification (131), but early insertion of polyethylene tubes and their regular replacement is not without complication and does not guarantee improvement in expressive language.

One upper airway abnormality that merits special mention is obstructive sleep apnea, a much underdiagnosed abnormality with multiple causes (133,134). Poor growth, noisy breathing, apnea–hypopnea, disturbed sleep, daytime sleepiness, and deterioration in behavior can all be consequences of nocturnal oxygen desaturation and chronic hypoxia. Treatments are not always successful but should be individually tailored in each case, with consideration given to weight control, relief of nasal allergies, and continuous positive airway pressure during sleep (135).

### 43.3.14 Ophthalmologic Disorders

Minor ocular findings in children and adults with DS include epicanthal folds, up-slanting palpebral fissures, and Brushfield spots on the iris (Figure 43-1). Asian children with DS seldom have Brushfield spots but do have epiblepharon and exotropia (136). Brushfield spots are also difficult to see in children with brown irides.

More important ocular complications, such as major refractive errors, cataract, glaucoma, nystagmus (137), nasolacrimal outflow drainage anomalies (138), and keratoconus (139), are important to detect. Therefore, all individuals with DS should have frequent visual screenings, starting in the neonatal period. One protocol suggests first examination at 1 month of age, then at 1 year of age, at 2–3 years of age, at 5–6 years of age (school start), and every 5 years thereafter (140). This should detect the accommodation deficit that is present in a majority of individuals and permit prescription of bifocal or progressive lenses.

### 43.3.15 Hematologic Disorders

Abnormalities affecting red cells, white cells and platelets are common in DS. At birth, 65% of DS infants have polycythemia (141). Interestingly, the mouse model of T21 demonstrates many of the same hematologic features of human DS including thrombocytosis, macrocytosis and a myeloproliferative disorder (142,143). Neutropenia and macrocytosis are also common in DS and the reasons are not known. Transient myeloproliferative disease (TMD) or transient leukemia almost exclusively affects infants with DS. Recent work in another mouse model for DS suggests that trisomy for the gene *ERG* may underlie this phenotype, as reduction to disomy for *ERG* corrected the myeloproliferative phenotype (144). The rate of TMD diagnosed prenatally or postnatally is 20%.

A reported prenatal presentation of TMD is that of generalized hydrops and is generally fatal (145) (Figure 43-3). Most cases of TMD are asymptomatic with resolution by 2–3 months of age, but some have severe disease (146,147). Presenting symptoms can include hepatosplenomegaly, obstructive jaundice, liver failure and ascites. Laboratory findings include leukocytosis; reduced, raised, or even normal platelet counts; and low, high, or normal hemoglobin. TMD is characterized by the presence of blasts in peripheral blood from a few to >200,000  $\mu$ L. With time the blasts decrease spontaneously. Unlike other forms of leukemia, the percentage of blasts in bone marrow is lower than in peripheral blood. Vesiculopapular skin findings are common, which may be a clue to the presence of TMD, and these findings resolve with hematological improvement (148,149).

Although spontaneous resolution in the first 3 months is usual, about 25% of affected children will, within 4 years, develop myelodysplastic syndrome and acute

megakaryoblastic leukemia (AMKL) (150). Rarely, life-threatening complications occur, including hepatic fibrosis and cardiopulmonary disease (151–154). White cell counts >100,000, direct hyperbilirubinemia, prematurity and hydrops with ascites are associated with increased risk of early death. Most patients do not require chemotherapy for TMD, but cases that do not resolve spontaneously or the high blast counts or liver dysfunction occasionally improve with low-dose cytosine arabinoside. Usually there is rapid response, with clearing of blast cells after about 7 days of treatment (155). When there is liver fibrosis the prognosis is poor, even with chemotherapy. The overall mortality in TMD is about 20% (154).

T21 specifically predisposes to leukemia, with a risk of 1–1.5% (156). The type of leukemia that has the highest relative risk of occurrence in T21 is AMKL. This leukemia arises in cells carrying somatic mutations in *GATA1*, an X-linked gene encoding a hematopoietic transcription factor seen invariably in AMKL, occurring prior to age four. In contrast, acute myelogenous leukemia diagnosed after age four is usually negative for *GATA1* mutations.

The leukemic cells in AMKL that carry somatic mutations in *GATA1* have been identified in transient leukemia blasts at birth, indicating that the somatic mutation occurs in utero (157). In one study of *GATA1* mutations, three of four children with a *GATA1* mutation detected in newborn screening blood spots had AMKL diagnosed at 12–26 months of age (158). Identification of *GATA1* mutations at birth could serve as a marker for the development of TMD and later AMKL. In a 2011 study, 88% of 134 DS patients with TMD had *GATA1* mutations and 85% of those DS patients with AMKL and DS had *GATA1* mutations (159). Thus, it is hypothesized that the leukemia that arises in DS with somatic *GATA1* mutations is a model for the stepwise process of leukemic transformation.

Another theory proposed by Da Vita and colleagues (160) is that disturbed early hematopoietic differentiation could be the cause of increased leukemia risk. They postulate that if a common mechanism is behind the risk of both major leukemia types, it would have to arise before the bifurcation to myeloid and lymphoid lineages. Using mouse embryonic stem cells bearing an extra human chromosome 21 they analyzed the early stages of hematopoietic commitment in vitro. They concluded that overdose of more than one extra 21 gene contributes to the disturbance of early hematopoiesis in DS and that one of the contributors is the gene *RUNX1*. As the observed hyperproduction of multipotential immature precursors in T21 precedes the bifurcation to lymphoid and myeloid lineages, they speculate that this could create conditions increasing the chance for acquisition of preleukemogenic rearrangements/mutations in both lymphoid and myeloid lineages during fetal hematopoiesis, thus contributing to the increased risk of both leukemia types in DS.

The risk of developing acute lymphoblastic leukemia (ALL) in DS is 10–20 times higher than in control children, accounting for 1–3% of children with ALL (161). Clinical symptomatology is similar to that seen in patients without DS. Mediastinal mass and CNS leukemia, unfavorable signs, are less likely to occur in patients with DS, as are T-cell leukemia and translocations 9;22 and 4;11. DS children, usually less than 10 years of age, respond to chemotherapy as well as control children with ALL. Children with DS are more likely to experience severe toxicity with standard chemotherapy regimens, particularly those requiring methotrexate, and often require reduced doses of chemotherapy (162,163).

Children with DS and ALL have an increased number of deaths caused by infection, a decreased five-year survival and more treatment-related complications as compared to children with ALL who do not have DS (150). These findings emphasize the need for providing aggressive supportive care for patients with DS and ALL.

### 43.3.16 Immune System Abnormalities

Abnormalities in virtually all components of the immune response have been reported in persons with DS. Commonly, immune system disturbances in DS manifest as a predisposition to infection, malignancies and autoimmune disorders, including celiac disease, diabetes mellitus, and autoimmune thyroiditis. Infections in DS are likely to be more severe and last longer than in typical children, and despite advances in treatment of infections, hospitalization due to infection is significantly more common in DS children. Immune factors are thought to play a role, but certainly the presence of tiny ear canals, gastroesophageal reflux and a small midface also contribute to infection risk.

The abnormalities of the immune system associated with DS include mild to moderate T- and B-cell lymphopenia, with marked decrease in naive lymphocytes, impaired mitogen-induced T-cell proliferation, reduced specific antibody responses to immunizations and defects of neutrophil chemotaxis. Limited evidence of genetic abnormalities secondary to trisomy of chromosome 21 affecting the immune system is available, such as the potential consequences of gene overexpression, most significantly superoxide dismutase (*SOD1*). Decreased intracellular killing in neutrophils is the most likely manifestation of a dosage effect from increased *SOD1* (164,165).

In a 2010 study, B-lymphocyte subpopulations in 95 children with DS were compared with 33 age-matched control children. DS serum immunoglobulin levels were compared with those of 962 non-DS children with recurrent infections. Transitional and naive B lymphocytes were profoundly decreased in the children with DS. This could be caused by an intrinsic B-lymphocyte defect resulting in (partial) failure of B-lymphocyte generation, decreased antigen-induced proliferation and/or increased

apoptosis, decreased proliferation due to deficient T-lymphocyte help, or a combination of these. The decreased number of CD27, CD21, and CD23 cells was reminiscent of common variable immunodeficiency and suggestive of disturbed peripheral B-lymphocyte maturation. Immunoglobulin levels in DS are subtly abnormal and different from those in non-DS children with recurrent infections. These authors concluded that the humoral immune system is abnormal in DS, but they could neither find a relation between B-lymphocyte subsets, immunoglobulins and clinical features of the children with DS nor answer the question whether DS lymphocytes are truly intrinsically deficient or are all findings explained by deficient T-lymphocyte helper cells (166). A 2011 study confirms the subtle abnormalities in the immune system and reports a normal antibody response to influenza vaccine but an impaired response to pneumococcal vaccine (167).

Immunologic alterations are often age related and may be one feature of a general, early-onset senescence in DS (168). The thymus in DS has histologic abnormalities that include reduced cortical area, thymocyte depletion, loss of corticomedullary demarcation, enlarged cystic Hassall corpuscles, and evidence of defective expansion of T-cell precursors. Reduced expansion of T-cell precursors may lead to an incomplete cell repertoire and abnormality of cell-mediated immune response. Evidence suggests that reduced thymic output and not peripheral output or T-cell dysfunction contributes the immunologic features of DS (169).

Most DS individuals do not have critical immunodeficiencies, but further study is needed to understand the immunologic role in their repeated infections. Immunologic evaluation should probably be reserved for those DS children with unusual and/or repeated infection, autoimmune disease, or other evidence of immunodeficiency.

Children with DS should receive the full childhood immunization schedule, including yearly influenza immunizations and pneumococcal vaccine. It is especially important for these children to receive hepatitis B immunization, as there is a significant risk for chronic carrier status (126).

### 43.3.17 Endocrine Disorders

Newborn infants with DS have levels of thyroid-stimulating hormone (TSH) and thyroxine slightly shifted to the right and left, respectively, compared with the general newborn population (170). A recommendation that all DS neonates should be treated for “mild congenital hypothyroidism” on the basis of evidence that mental and motor development is improved in thyroxine-supplemented infants (171) requires further assessment. Treatment is definitely required for severe congenital hypothyroidism due to thyroid gland dysgenesis. There has been the general conviction that hypothyroidism is frequent in DS, with a frequency varying between 3 and

54% in DS adults (172). In view of the high frequency of hypothyroidism and the nonspecificity of symptoms and clinical signs such as lethargy, increased weight, constipation, depression, and dementia, regular surveillance seems indicated. Health care guidelines published by the American Academy of Pediatrics (15) suggest regular checks of thyroid antibodies and thyroxine and TSH measurements at 1–2 year intervals. A 15-year follow-up study of hypothyroidism in 200 DS adults suggests that clinical hypothyroidism is relatively uncommon and that screening guidelines could be revised to suggest testing only every 5 years (173).

The risk of type 1 diabetes appears to be increased in DS (174). Interestingly, in one study, age of onset of diabetes was significantly earlier than in controls but diabetic control was better than in controls and less insulin was required. Accompanying additional autoimmune disorders were more frequent than in controls with type 1 diabetes (175). Diabetes was more likely to occur in females and in those with obesity (176).

Fertility in DS differs by sex, with males being generally infertile. This is probably due to impaired spermatogenesis. A 2002 study of young adult males with DS revealed normal levels of FSH, testosterone and dehydroepiandrosterone but showed elevated levels of luteinizing hormone (LH) and 17-OH progesterone (100). Rarely there have been reports of fertility in males. Females with DS appear to have normal menarche (12.6 years). There may be subtle abnormalities of the pituitary–adrenal axis, with increased levels of prolactin, LH, testosterone and 17-OH progesterone (100). DS women appear to have reduced fertility, but this may be due to lack of opportunity. Pregnancy has been reported on multiple occasions. Appropriate counseling and contraception are indicated for DS women. A higher rate of early menopause has been reported in women with DS (177).

### 43.3.18 Craniovertebral Junction Abnormalities, Including Atlantoaxial Subluxation

Atlantoaxial subluxation is a serious but infrequent complication of DS that causes neurologic symptoms and signs of spinal cord compression, including sudden or gradual onset of neck pain or postauricular pain, head tilt, ataxia, limb weakness, loss of bowel or bladder control, increased tendon reflexes, and spasticity. Such signs may occur at any age and are an indication for immediate referral to a specialist for investigation and, in some cases, surgical treatment (178).

In contrast, atlantoaxial instability is defined radiologically as an atlantoaxial gap of greater than 4 mm that may be observed, without any symptoms or clinical signs, in lateral-view radiographs of the cervical region in full flexion and extension. Instability probably does not predict increased risk of cord compression and seems to

have little or no predictive value for subsequent acute dislocation or subluxation at the atlantoaxial joint, such as might occur with a sports trauma or neck manipulation in the course of unguarded anesthesia (179,180). The American Academy of Pediatrics committee on genetics advises that a single radiograph should be obtained and such a radiograph may be required by organizations such as the Special Olympics prior to the child's or adult's active participation (15).

In older DS adults, the degree of ligamentous laxity lessens but degenerative cervical spine abnormalities may occur.

### 43.3.19 Neurologic Problems

Epileptic seizures are more common in DS individuals than in the general population. The prevalence of seizures peaks in infancy and in late adult life. Diagnosis remains clinical and is crucially dependent on a reliable history and accurate observation (181). The electroencephalogram may clarify the type of epilepsy and help manage treatments of certain epilepsies. Infantile spasms, myoclonic epilepsy, clonic seizures, reflex atonic seizures, and febrile seizures have all been reported.

In adults, onset of epileptic seizures, especially myoclonic epilepsy, is associated with the onset and progression of dementia (182,183). Other signs of dementia are personality change, cognitive decline, gait deterioration, loss of daily living skills, and incontinence. Functional decline in adults with DS is also a feature of treatable conditions such as depression and hypothyroidism.

The prevalence of dementia in DS rises from 10% at 50 years to more than 75% at over 60 years of age. Males with DS are more likely to become demented. Genotyping within 43 single-nucleotide polymorphism (SNPs) within 28 genes revealed significant associations with *APOE*, *SORL1*, *RUNX1*, *BACE1* and *ALDH18A1*, with the strongest associations with *APOE* (184).

Alzheimer's in DS is characterized by a specific type of slow and progressive neurodegeneration, which involves the abnormal hyperphosphorylation of the microtubule associated protein (MAP) tau. This hallmark, called neurofibrillary degeneration, is seen as neurofibrillary tangles, neuropil threads, and dystrophic neuritis. Apparently required for the clinical expression of AD, and related tauopathies, it leads to dementia in the absence of amyloid plaques. While normal tau promotes assembly and stabilizes microtubules, the nonfibrillized, abnormally hyperphosphorylated tau sequesters normal tau, MAP1 and MAP2 and disrupts microtubules. The abnormal hyperphosphorylation of tau, which can be generated by the catalysis of several different combinations of protein kinases, also promotes its misfolding, decrease in turnover, and self-assembly into tangles of paired helical and or straight filaments. Some of the abnormally hyperphosphorylated tau ends up both amino and C-terminally truncated. Disruption of microtubules by

the nonfibrillized abnormally hyperphosphorylated tau, as well as its aggregation as neurofibrillary tangles, probably impair axoplasmic flow and leads to slow progressive retrograde degeneration and loss of connectivity of the affected neurons (185).

Neuropathologic studies of adults with DS reveal cerebral amyloid (amyloid) plaques and neurofibrillary tangles. In young DS patients, there is evidence of intraneuronal amyloid in the hippocampus and cerebral cortex, and it is proposed that intracellular deposition precedes extracellular amyloid, followed by diffuse and neuritic plaques in the third decade and neurofibrillary tangles after age 40 years (186,187).

Patients with Alzheimer dementia have reduced cerebral production of choline acetyl transferase, which leads to a decrease in acetylcholine synthesis and impaired cortical cholinergic function. Adults with T21 might benefit from acetylcholinesterase inhibitors, which in clinical trials have conferred benefits to mildly and moderately affected Alzheimer disease patients. Results from treating small-sample-size populations of DS individuals have been favorable, but larger randomized studies are required (188).

### 43.3.20 Trisomy 21: Factors Influencing Chromosome Nondisjunction

Hassold and Sherman (189) reviewed their own studies and those of others who examined chromosome 21 DNA polymorphisms to demonstrate that approximately 90% of T21 cases result from a maternal meiosis nondisjunction error, 75% of which occur at maternal meiosis I. In cases in which the extra chromosome is paternal in origin, meiosis I and meiosis II nondisjunctions are equally frequent. The low frequency of a paternal origin may be due to a very low percentage of testicular mosaicism as compared to that seen in the ovary (190). Mosaic T21 may have postzygotic origin or be caused by a maternal meiotic error leading to trisomy in the zygote followed by loss of the extra chromosome during a mitotic cell division (191).

Chromosome recombination in oocytes occurs before birth, and the pattern of chromosome 21 genetic recombination affects susceptibility to nondisjunction (192,193,194). In one study, younger mothers of T21 cases had more pericentromeric and telomeric exchanges that increase susceptibility to nondisjunction, whereas older mothers of T21 cases had exchange patterns that mimicked the patterns observed in normally disjoining chromosome 21s. This, it was argued, suggested that the greatest risk factor for nondisjunction in younger women is a susceptible exchange pattern (195). The "two-hit" model suggests that ovaries of older women may be less efficient at "rescuing" the susceptible-to-nondisjunction meiosis I exchange pattern because of age-related perturbations in meiotic machinery (194). The spindle checkpoint delays the cell cycle when meiotic or mitotic

chromosomes are not properly attached to the spindle; spindle checkpoint proteins are being investigated to determine if gradual decline in the efficiency of the checkpoint explains maternal age-related probability of aneuploidy (196,197).

As maternal age-adjusted DS rates vary little across human populations (198), these are unlikely to be greatly influenced by environmental factors such as periconceptional multivitamin use (199), but putative associations such as between poor socioeconomic status and maternal meiosis II error, and between parity and DS, have been examined (200,201). Other factors put forward that might influence nondisjunction rates include changes in follicular development unrelated to the size of the oocyte pool (202,203); reduced ovarian complement, whether due to congenital absence or surgical removal (204); and accumulation of spontaneous mitochondrial DNA deletion mutations that diminish the supply of energy to cells surrounding the oocyte (205). Inheritance of methylenetetrahydrofolate reductase (MTHFR) gene polymorphisms has been linked to chromosome 21 nondisjunction. Examination of transmission frequencies of the MTHFR 677T and 677C alleles from heterozygous parents to children with DS revealed that the 677T allele was transmitted to children with DS at a significantly higher rate and the 677C allele was transmitted at a significantly lower rate (206). Most conceptions with T21 end in pregnancy loss, and it was proposed that preferential transmission of the 677T allele in this population of live-born infants with DS could reflect a survival advantage. A putative association between birth of a child with folate-associated neural tube defect or hydrocephalus and increased risk of T21 is controversial (207,208). A 2010 study looking at predisposition to congenital heart disease in DS studied a group of 121 case families (mother, father, and proband with DS and CHD) and 122 control families (mother, father, and proband with DS and no CHD); tag SNPs were genotyped in and around five folate pathway genes: 5,10-MTHFR, methionine synthase (MTR), methionine synthase reductase (MTRR), cystathionine beta-synthase (CBS), and the reduced folate carrier (SLC19A1, RFC1). SLC19A1 was found to be associated with CHD using a multilocus allele-sharing test. In addition, the known functional polymorphism MTHFR C1298A was overtransmitted to cases with CHD and undertransmitted to controls. The authors concluded that the disruption of the folate pathway contributes to the incidence of CHD among individuals with DS (209). In summary, altered patterns of genetic recombination appear to be a common risk factor for T21 and for other maternal meiosis I trisomies, but the size and direction of the alteration varies with the chromosome involved (210). In addition, alterations in the folate pathway genes may impact the occurrence of congenital heart disease and possibly other defects in DS. A chromosome-nonspecific tendency to nondisjunction may explain why there is a slight excess of

other autosomal aneuploidies in women who have had a DS pregnancy at a young age (see “Down Syndrome Recurrence Risks” later) (211,212).

### 43.3.21 Chromosome 21 Down Syndrome Critical Region

Identification of cases with clinical features of DS in association with duplication of specific regions of chromosome 21 (Figure 43-5) led to the designation of a “Down syndrome critical region” at 21q22qter, hypothesized to harbor the most influential genes, extra copies of which determined most if not all DS features (213). At the same time, the “developmental instability” hypothesis proposed that DS features arose from specific disruptions of genetic homeostasis rather than from direct gene dosage effects (214). Fitzpatrick (215) incorporated both ideas in a testable hypothesis, proposing primary gene dosage abnormalities with sequential and complex transacting effects on disomic genes. Experimental evidence followed publication of the chromosome 21 DNA sequence with detailed annotation revealing over 200 genes, which is only half the number of genes on chromosome 22 (216,217).

Mouse models of DS have been generated because of the synteny existing between human genes on chromosome 21 and mouse genes on chromosome 16 (26.5 Mb), chromosome 10 (2.3 Mb) and chromosome 17 (1.1 Mb). Two kinds of murine models have been developed to investigate the molecular genetics of DS: segmental trisomic and transgenic models (218). The trisomic mouse mimics much of the clinical phenotype of DS, but single gene effects are difficult to analyze. In the transgenic mouse the effects of one or few genes can be studied in detail. Detailed statistical analysis of cranial shape in different trisomic mouse models (Ts1Cje, Ts65Dn, and Ms1Rhr/Ts65Dn) have shown that DS critical region genes alone are neither sufficient nor (largely) necessary to produce characteristic mouse craniofacial dysmorphology (219). This important study proposed that, in DS, triplicated genes have inconspicuous solitary effects but do contribute to the overall phenotype in combination with other genes, through as yet unidentified specific effects and interactions. Gene expression studies in Ts65Dn mice also point to complex regulation of expression of the aneuploid genes, since only a third are expressed at the theoretical 1.5-fold level, with significant proportions being expressed at levels above and below 1.5-fold (220). In yet another mouse model, there is evidence that triplication of the genes in the DS critical region does confer a characteristic neurological and behavioral phenotype (221). In several transgenic mouse models the important genes in the critical region, DYRK1A and RCAN1, have been shown to contribute to the learning and memory deficit, altered synaptic plasticity, impaired cell cycle regulation, and AD-like neuropathology in DS (222). Increasing evidence suggests that there is not

a single DS critical region but a number of susceptibility regions on chromosome 21, which are modified by other genes on chromosome 21 and genes elsewhere in the individual's genome. A review by Ruparelia and colleagues (223) summarizes how overexpression of genes on chromosome 21 contributes to the pathogenesis of DS. Whether or not the mouse phenotypes are directly applicable to high-level behavior and learning necessary for normal human development remains unclear. Nevertheless, better understanding of the complex genetic origins of the abnormal behaviors in the mouse model as well as illustrative human case reports, aid human DS genotype-phenotype analysis (224,225).

### 43.3.22 Down Syndrome Recurrence Risks

**43.3.22.1 Trisomy 21 and Mosaic Trisomy 21 Recurrence Risks.** Hook (226) summarized data on the chance of recurrence of T21 in children of mothers who had one live-born affected infant: when the mother was of age under 30, the recurrence risk was 1.4%, and this figure was clearly increased above the background rate of about 0.7%. But when the mother was older, the T21 recurrence risk was not clearly increased above the background maternal age risk. Hook also reviewed evidence from amniocentesis data that older women who had their first affected pregnancy under age 30 were more likely to have greater underlying predisposition to recurrence compared with older mothers who had their first affected pregnancy after age 35 years.

Hook's conclusions were confirmed in three more recent studies. Employing North American, United Kingdom and Australian data, Warburton and colleagues (227), De Souza and colleagues (212) and Morris and coworkers (5) compared observed numbers of trisomies at prenatal diagnosis with expected numbers. Comparisons of recurrence rates after diagnosis of the same trisomy (homotrisomy) and of a different trisomy (heterotrisomy) showed that younger women had the highest recurrence risk for homotrisomy, with both the index T21 and subsequent prenatal diagnosis at age less than 30 years. The risk was less for women with both pregnancies at age greater than or equal to 30 years. The study from the United Kingdom (4) showed women who had had a previous DS pregnancy have a constant absolute excess risk above their maternal age-related risk of having a subsequent affected pregnancy. The excess was determined by the age at which the affected pregnancy occurred and was considerably higher for women less than 30 years and negligible in women greater than 40 years.

When counseling families, these various recurrence risks may be perplexing. One approach is to emphasize that the overall chance of recurrence of T21 is still low: at about 1% at the time of prenatal diagnosis for mothers less than 30 years of age, this figure represents a six- to eightfold increase in the age-related risk; for mothers aged 31–40 years who had the index case in their 30s, the

age-related risk may be doubled; and for mothers over 40 years, there is negligible change in the maternal age-related risk. The chance of recurrence for any other viable trisomy after an index case with T21 may be double the age-related risk.

#### 43.3.22.2 Two Previous Trisomy 21 Conceptions.

About 3% of couples have a greater risk of recurrence of DS because of the presence of somatic or gonadal chromosome mosaicism in one parent (228). Such couples might have three or four pregnancies affected by trisomy 21. De novo recurrence of the same trisomy is another possibility, but studies suggest that the origin of recurrence is much more likely to be due to low-level oocyte mosaicism (228,229). Kovaleva (228) and Delhanty (229) evaluated records or literature reports on 80 families with recurrent T21. Postzygotic rescue of T21 due to error in meiosis I was proposed as a mechanism of parental gonadal mosaicism formation in 78% of the families with known origin of the T21. For the other 22%, rescue of errors in meiosis II or postzygotic mitotic nondisjunction was assumed. Mosaicism for T21 in successive generations has been reported in at least 12 families. Kovaleva and Delhanty (229) hypothesize that in many cases the mother was a trisomic conception with postzygotic trisomy rescue. It is interesting that in proven maternal mosaicism the maternal grandmother was over 35 at the time of the mother's conception. Parental gonadal mosaicism (mostly maternal) may contribute significantly to the occurrence and recurrence of DS in young women. In counseling of families with a recurrence, a suggested 10–20% represents an educated guess for the risk of a third pregnancy with T21. Preimplantation genetic diagnosis may be an option for some families with an apparently high recurrence risk (230).

**43.3.22.3 Parent with Trisomy 21.** Women with T21 may become pregnant, and in this situation the risk of T21 in the offspring is close to 50%. Fertility in males with T21 is exceptional, but there are at least three well-documented reports of an affected male fathering an unaffected child (231).

**43.3.22.4 Translocation and Isochromosome 21 Down Syndrome.** Following the diagnosis of translocation 21 or isochromosome 21 DS, if both parents have normal blood chromosomes, the translocation or isochromosome is usually presumed to have arisen as a result of a new mutation (de novo), and the observed recurrence risk in a series of translocation cases was less than 1% (232). Gonadal mosaicism for isochromosome 21 has been reported and recurrences of DS are recorded (233), so a rounded-up 1% risk of recurrence is appropriate, and prenatal cytogenetic diagnosis should be offered to cytogenetically normal parents who had a fetus or child with DS due to a de novo structural abnormality.

Where one parent is shown to carry a balanced Robertsonian translocation that has given rise to a child affected by DS, the risk of recurrence mainly depends on the sex of the carrier parent: if the mother is a

rob(14q21q) carrier, the risk of recurrence at amniocentesis is 15% (closer to 10% at term because of fetal demise after 16 weeks' gestation), compared with a much lower risk of less than 5%, even less than 1%, if the father is the translocation carrier. In parental translocation carriers of both the 14/21 translocation and the 13/14 translocation recurrence risk data was confirmed in a study of embryos from preimplantation genetic diagnosis (234). Although data are scanty, the same risks and sex difference most probably apply to other heterologous Robertsonian translocations involving chromosome 21 (rob(13q21q), rob(15q21q), and rob(21q22q)).

Translocation interchange T21 is a rarer cytogenetic variant that has been reported in more than 20 families with reciprocal translocations involving chromosome 21q. Usually, a large chromosome (numbers 1 through 12) is involved, and there is underlying 3:1 segregation, most often in the carrier mother, with a high risk of recurrence (235).

**43.3.22.5 Family History of Down Syndrome.** When the proband has confirmed T21, relatives other than the proband's parents may be advised that their positive family history does not confer an appreciably increased risk of T21, except, of course, when the family history absolutely suggests otherwise. Gair and colleagues (236) reported one such family with four cases of T21 in three generations.

In the case of an affected individual with unknown karyotype, based on the mother's age at the birth of the proband, the probability of translocation DS is very low when the mother is over 35 years and no greater than 10% at the youngest maternal age. Therefore, chromosome analysis carried out on a parent with a positive family history of DS rarely discloses a balanced Robertsonian translocation. Chromosome analysis may be offered to an expectant relative with explicit understanding that a normal result does not abolish risk of an abnormal pregnancy outcome. Aside from other chromosomal or inherited syndromes being mistaken for DS, cryptic or submicroscopic translocation involving chromosome 21q may cause recurrent DS with a normal karyotype (72).

## 43.4 TRISOMY 18

T18, or Edwards syndrome, was first diagnosed cytogenetically 1 year after T21 (237). It is the second most common trisomy. Neonatologists and pediatricians are usually familiar with the characteristic presentation and medical course of this serious trisomy.

### 43.4.1 Clinical Diagnosis

T18 is usually not a difficult clinical diagnosis, but may present difficulties to less experienced clinicians and in the setting of a neonatal resuscitation when the phenotype may be more challenging to appreciate. The

craniofacial features include dolichocephaly and a small triangular face that is seen by parents as "cute" but to the professional as distinct. The forehead is high, occupying more than one-third of the face. The nasal bridge is high for age and palpebral fissures often slant down and are short. The mouth is characteristically small, making intubation difficult. There is accompanying micrognathia. The ears have been called "windswept" because of posterior rotation and the helices are often poorly delineated. Preauricular tags and pits are not infrequent. The sternum is subjectively and objectively short. The hands reveal overlapping fingers, second and fifth over third and fourth (Figure 43-4). Nail hypoplasia is a consistent finding and is very helpful diagnostically. Phalangeal flexion creases are reduced to absent, especially distally. Prominence of the heels with convexity of the soles (rocker-bottom feet) and short, dorsiflexed great toes with a slight degree of second and third toe syndactyly are useful signs (Figure 43-5). The genitalia are often underdeveloped, with a characteristic decrease in fat stores of the mons veneris area in females. The neurological exam can reveal either hypotonia or hypertonia. General responsiveness is decreased and apnea/bradycardia are frequent findings. Structural birth defects are common, including congenital heart disease, esophageal atresia, omphalocele and the Dandy Walker malformation and its variants.

### 43.4.2 Prenatal Diagnosis

The prenatal diagnosis of T18 is accomplished by a variety of means depending on when the mother presents in pregnancy. There is increasing diagnosis in the first trimester because of early serum screening, NT determination and characteristic sonographic findings. In one study of 53 cases of T18 in the first trimester, all but one fetus had one or more sonographic abnormalities, the most common of which were an increased NT (91%), hypoplastic nasal bone (53%), generalized subcutaneous edema (49%), omphalocele (21%) and early growth restriction and bradycardia (26%) (238). This study confirms reports by Breathnach et al. (50) and Wapner et al. (239). First-trimester serum screening showing decreased levels of PAPP-A and decreased beta hCG are also helpful and may direct patients to early definitive testing via chorionic villus biopsy.

In mothers presenting for the first time in the second trimester there are a number of helpful diagnostic modalities. Serum quadruple screening provides useful information, which in combination with ultrasound can lead to accurate detection via invasive testing or a high suspicion of this diagnosis in women declining amniocentesis. The most common second-trimester findings in T18 include congenital heart disease, posterior fossa abnormalities in the Dandy Walker spectrum, choroid plexus cysts, and ventriculomegaly (240,241). Craniofacial abnormalities are frequently diagnosed by ultrasound with some specificity as to the chromosome involved (242). An isolated

**FIGURE 43-4** Two infants with trisomy 18. Note triangular face, small mouth, downsloping palpebral fissures, overlapping fingers, and short sternum.

**FIGURE 43-5** Trisomy 18. (a) Overlapping fingers in fetus. Note severe nail hypoplasia. (b) Rocker bottom foot.

choroid plexus cyst is a frequent normal developmental finding, which resolves in the third trimester, and in the absence of other findings is unlikely to be due to T18 (55). On the other hand, large and/or multiple choroid plexus cysts in the presence of other consistent anomalies are strongly suggestive of T18. A study by Lai and colleagues (243) reviewed 10 years' experience with 69 diagnoses of T18. The detection rate of fetal anomalies by ultrasound was 93% at <14 weeks and 100% at 18–21 weeks. A normal detailed ultrasound with normal fetal growth and normal amniotic fluid in the midtrimester essentially rules out T18.

A definitive diagnosis of T18 by chorionic villus biopsy or amniocentesis should prompt careful counseling of the family, which should take into account the family's cultural and religious beliefs. Most families receiving this diagnosis will elect termination after considering fully this serious handicapping condition. Some families will want to continue the pregnancy and should be supported in this decision (244). There should be a dialog between the obstetric/neonatal team and the family to achieve decisions that will be "in the best interests of the child." The practice of prenatal consultation with the family and

the neonatal team should be encouraged so that a birth and neonatal plan can be agreed upon prior to delivery. Merritt and colleagues (245) present an excellent comprehensive review of these complicated issues. Avoidance of cesarean section when fetal distress occurs in labor should be proposed to the family. Optimally the family will decide on vaginal delivery and supportive comfort care for the infant. Some families insist on "doing everything" for the baby even when all the facts are presented. This clearly presents a conflict between the physician's understanding of the medical facts and families' desire for autonomous decision making for their infant. In general, obviating the infant's pain and suffering and avoiding escalation of care, including intubation, should be goals for both families and treating physicians. These situations may present serious ethical challenges to the health care team (245–247). Ethical issues more commonly arise when there is no knowledge of a definitive diagnosis prenatally because of late prenatal care, refusal of diagnostic testing, or parental denial of the findings on ultrasound. In these situations, urgent consultation after birth by an experienced geneticist can lead to confirmation of the suspected clinical diagnosis and fact-based

supportive counseling. Utilization of a neonatal palliative care team, if available, and use of local infant hospice resources should be encouraged and can help families and health care providers achieve mutual goals for the infant and family. Even with full intervention including surgery and ventilator support the outlook for long-term life seems not to be improved, and these are the facts that families should understand in their decision-making.

A clinical diagnosis should always be confirmed by a postnatal karyotype or FISH. Array comparative genomic hybridization (array) will also confirm this diagnosis, but is an expensive option when the clinical diagnosis is unambiguous. FISH and array studies can be particularly useful on formalin fixed tissue when the infant is still-born and/or macerated and routine karyotyping is not successful.

### 43.4.3 Natural History

Case reports, epidemiologic studies, and interviews with parents have provided data on the natural history of T18 (7,248–252). After cytogenetic confirmation or a firm clinical diagnosis, parents may be told that median survival is 1–2 weeks, 90% of babies die by 6 months, and only 5–10% are still alive at age 1 year. Congenital heart disease or cardiopulmonary arrest are frequently stated to be the cause of death in T18, but this may be an oversimplification, with ill-defined CNS abnormalities and respiratory system problems contributing to “central apnea” (246).

Cardiac anomalies are common in surviving infants, with cyanosis present in the majority of newborns. The most common lesions are large septal defects and patent ductus arteriosus. Valvular dysplasias are present in most cases but are not associated with significant regurgitation or stenosis. Doppler evidence suggestive of elevated pulmonary artery pressure (low-velocity bidirectional flow across the ventricular septal defect and patent ductus arteriosus) is accompanied by greater than normal mean right ventricular cavity and free wall dimensions. The combined findings of frequent cyanosis and increased right ventricular dimensions suggest that factors such as pulmonary hypertension may contribute to early death. Cardiac surgery is not usually performed in the United Kingdom and Europe, but is more frequently undertaken in the United States and Japan (253). A recent survey of clinicians caring for these infants suggested that care takers often do not agree on their approach to recommending or offering surgery to these infants, with cardiologists more likely to offer intervention than neonatologists or geneticists (254). The literature on infants who have undergone full therapeutic interventions is not encouraging with respect to improving long-term survival. One study examined the outcomes of cardiac surgery in 34 patients with T18. Survival over the short term was statistically slightly better in the group of nine undergoing surgery, but the rate

of being discharged home alive was no different in the two groups (255).

In older survivors, profound physical and intellectual disability is inevitable and overall development usually does not progress beyond that of a 6-month-old, chromosomally normal infant. Vision and hearing impairments may be severe (256). Somatic growth is poor (257), and skeletal abnormalities such as severe kyphoscoliosis are frequent (258). Infection causes morbidity and mortality (259). Various malignant tumors are infrequently reported, including Wilms tumor (260) and hepatoblastoma (261).

### 43.4.4 Differential Diagnosis

“Pseudo-T18 syndrome” was formerly diagnosed in infants with some signs of T18, such as prominent occiput, abnormal ear helices, short palpebral fissures, distal limb contractures, and profound developmental retardation, who had a normal karyotype. Pseudo-T18 is practically never diagnosed today, but syndrome delineation in such challenging infants remains difficult. A rare condition that may resemble T18 includes Bowen-Conradi syndrome caused by mutations in the ribosome biogenesis gene *EMG1*. Infants with this autosomal recessive condition first described in the Hutterites, have many of the same features seen in T18 and have an equally poor prognosis for life and mental development (262). The heterogeneous Marden-Walker syndrome may have similar hand findings along with an immobile face and growth restriction. The complex and heterogeneous syndromes termed Pena Shokeir or cerebral ocular facial syndrome (COFS) are encompassed by the term fetal akinesia deformation sequence (FADS). This phenotype can be seen when a mother has myasthenia gravis with high titers of anti-acetylcholine receptors (263). In addition, FADS can be caused by homozygous mutations in *DOK7* or *RAPSN* (264,265). Other autosomal recessive causes of FADS await gene discovery. Autosomal recessive variegate aneuploidy with multiple mosaicism including T18 cells has also been reported. Using exome sequencing, this was recently found to be due to homozygous mutations in *CEP57*, a centrosomal protein involved in nucleating and stabilizing microtubules. The study indicates the crucial role of *CEP57* in maintaining correct chromosome number in cell division (266). Distal arthrogryposis may present in the newborn period with a T18-like hand, but lack of other features such as growth restriction and major anomalies reflects its much better prognosis.

### 43.4.5 Mosaic Trisomy 18

The phenotypes displayed by cases of T18 mosaicism range from full T18 syndrome through a milder, non-specific, dysmorphic phenotype often but not always

associated with growth deficiency (266) to a normal phenotype in cases ascertained serendipitously. If blood chromosomes are normal, clinical signs such as asymmetry of body proportions or cutaneous pigmentary abnormalities (267) are indications to undertake cytogenetic analysis of skin fibroblast cultures. Conversely, full T18 in blood cells with an unexpectedly mild clinical course should suggest chromosome mosaicism with a euploid cell line in other tissues (268).

#### 43.4.6 Cytogenetics of Trisomy 18

T18 syndrome is almost always due to three copies of chromosome 18, and, like T21, T18 is a maternal age-related autosomal trisomy with the rate at prenatal diagnosis or birth rising until 43 years and then leveling off (269). Studies employing polymorphic DNA markers indicated that the extra chromosome in T18 is usually of maternal origin; however, in contrast to T21, wherein maternal meiosis I errors are most frequent, maternal meiosis II errors predominate in T18 (193). Chromosome-specific factors complicate the simple model of susceptible chiasma distributions interacting with age-dependent deterioration of the meiotic mechanism. For chromosome 18, 30% of tetrads are nullichiasmate in maternal meiosis I nondisjunction, but nullichiasmata are not observed in maternal meiosis II nondisjunction. Maternal meiosis I errors, paternal meiosis errors, and post-zygotic errors do occur in a minority of T18 cases (270).

Very few cases are associated with translocations or any other chromosome 18 structural abnormalities such as the true 18q isochromosome (271). Detailed phenotype–karyotype correlations have thus been possible in a few cases only and led to the conclusion that no single region on 18q is sufficient to produce the T18 phenotype. Proximal and distal regions of 18q are both important, and severe mental retardation is associated with 18q isochromosome (272,273).

#### 43.4.7 Trisomy 18 Recurrence Risk

Recurrence of T18 is exceptionally rare, but over 40 years ago Hecht and colleagues (274) suggested increased risk of DS in families in which the index case had T18. Since then, there have been many recorded instances of occurrence in a sibship of T18 followed by or following a different trisomy (heterotrisomy). Recurrence of heterotrisomy cannot be accounted for by gonadal mosaicism in one parent. The risk of recurrence of heterotrisomy after a T18 index case is low, but in view of the evidence for predisposition to aneuploidy in younger women (227), highest risk estimates might be, first, for young mothers (<30 years) who have had an index case with T18, and a rounded-up 1% at the time of prenatal diagnosis may be offered as the chance of recurrence of any viable autosomal trisomy. In the case of mothers aged

30–40 years, twice the maternal age-related risk for DS represents the highest risk; for mothers over 40 years, the maternal-age specific risk of occurrence of trisomy is the best estimate. Prenatal diagnosis utilizing serum markers and ultrasound is customarily offered and some families will desire amniocentesis or chorionic villus sampling (CVS) for maximum reassurance.

If the T18 phenotype results from a chromosome 18 balanced structural rearrangement present in one parent, the risk of recurrence will almost always be significantly higher, but a more precise risk estimate will depend on the type of rearrangement and the pattern of its segregation in the extended family tree.

### 43.5 TRISOMY 13

In 1960, Patau and coworkers (275) reported T13 syndrome in the same issue of *The Lancet* that contained Edwards and colleagues' description of T18. That T13 infant had an extra D-group acrocentric chromosome, microcephaly, anophthalmia/microphthalmia, bilateral cleft lip and palate, and polydactyly. Notably, she was still alive at 13 months. The classic T13 syndrome phenotype was highly distinctive and had almost certainly been the subject of detailed case reports in earlier centuries (276).

#### 43.5.1 Clinical Diagnosis

A maternal history of severe and/or early-onset pre-eclampsia may be a prenatal clue to this diagnosis (277). Pre- or postnatally, the placenta may be recognized as abnormal or show changes similar to those present in a partial or mole (278). The mean birth weight is reduced at 2.6 kg. Postaxial polydactyly of the hands and feet plus any combination of microcephaly, ocular malformation (anophthalmia/microphthalmia), cleft lip and palate, heart defect, or renal abnormality is typical (Figure 43-6). Scalp defects in the region of the posterior fontanelle and present in nearly 50% of cases, are diagnostically helpful. Cardiac abnormalities, usually septal defects, occur in over 80% of cases. These defects are rarely the cause of infant death, that is more likely to be on a central basis.

Holoprosencephaly is present in about 66% of cases, with the face malformation (synophthalmia or hypotelorism and premaxillary agenesis) frequently, but not always, “predicting” the brain malformation. The cerebral malformation usually comprises a monoventricular cerebrum without corpus callosum, septum pellucidum, or fornices. Posterior fossa intracranial abnormalities with cerebellar malformation and heterotopias, microscopic abnormalities with pyramidal tract hypoplasia, neural tube defects, and cortical dysplasia are included among neuropathologic features of T13 that are neither constant nor obligatory (279). The diagnosis of T13 should always be suspected in an infant with holoprosencephaly and other anomalies. Occasionally the diagnosis

**FIGURE 43-6** Trisomy 13. (a) Typical face with bulbous nose and microphthalmia. Note postaxial polydactyly. (b) Typical scalp defects in trisomy 13.

of T13 can be unexpected, as when features of the Potter sequence obscure the craniofacial findings (personal experience).

Other pathologic findings in affected fetuses and infants include atrial and ventricular septal defects with patent ductus arteriosus, omphalocele, incomplete intestinal rotation or malrotation with unattached mesentery, enlarged lobulated kidneys with cystic change in the cortex and medulla, accessory spleen, abnormal liver lobation, microscopic pancreatic dysplasia, and changes in the morphology of the axial skeleton (280).

### 43.5.2 Prenatal Diagnosis

Prenatal diagnosis of T13 is common and increasingly cases are diagnosed in utero at 10–14 weeks on the basis of ultrasound abnormalities. The most common finding in the first trimester is increased nuchal edema (281), with about one-third of fetuses with this presentation having chromosome abnormalities, chiefly trisomies 21, 18, and 13 and Turner syndrome. Even more predictive of a chromosome abnormality is cystic hygroma in the first trimester as about half these fetuses will have chromosome abnormalities. Later in pregnancy hydrops fetalis is relatively common occurring in about 5–10 of T13 fetuses (282).

Congenital heart disease is seen in over 90% of T13 fetuses and infants, with the most common defects being ventricular septal defects, atrial septal defects, patent ductus, hypoplastic aorta, mitral and aortic valve abnormalities, pulmonic stenosis and total anomalous pulmonary venous return. Prenatal detection of these defects by ultrasound is high, averaging about 50% in multiple series (282).

Other major birth defects are common in T13 and can be detected as early as the first trimester. Reviewing

the published series, Chen noted omphalocele in 15% of fetal T13 and diaphragmatic hernia in 6–13% (282). Severe urinary tract malformations including most commonly hydronephrosis and rarely renal agenesis are reported in as many as 37% of T13 fetuses. Postaxial polydactyly seen in about 50% of T13 infants and about 25–60% of these anomalies are detected prenatally on ultrasound. Brain abnormalities, most commonly those in the holoprosencephaly spectrum, may also be suspected in the first trimester (283,284) and is the most common abnormality associated with T13. Its presence in a prenatal sonogram, especially when other abnormalities are documented, is highly suggestive of a diagnosis of T13.

### 43.5.3 Management

Given the evident seriousness of the malformations present in most affected infants, the immediate management of newborn infants with T13 and subsequent management of children with T13 raises ethical problems similar to those encountered in relation to management of T18 or other seriously malformed infants and children (discussed earlier). Median survival in T13 is less than 1 week (7), and more than 80% of affected infants die during the first month, but about 3% are alive at 6 months. If major congenital heart and renal defects are present, surgery is usually not undertaken. The issue of cardiac surgery may become important if the child survives to 2–3 months and is developing pulmonary hypertension. One series of nine patients who underwent surgery with trisomy 18 or 13 found that four of the nine remained alive at age 2 years (285). Individuals surviving to childhood and adulthood with T13 who do not have life-threatening malformations have profound intellectual impairment, severe sensory impairments, epilepsy, and

feeding difficulties, as well as difficult behaviors such as self-mutilation (246).

Decisions regarding management need to be made jointly by care providers and families. These decisions include whether or not to use oxygen and monitors or whether or not to consider intervention for cardiac disease. Usually the decision not to treat is considered “in the best interests of the child,” but decisions need to be individualized and accompanied by careful counseling (246).

#### 43.5.4 Differential Diagnosis

The overall pattern of anomalies in T13 usually allows for a rapid clinical diagnosis. There is significant overlap of the major features with other multiple congenital anomaly syndromes. The presence of postaxial polydactyly may suggest the diagnoses of Meckel–Gruber syndrome or Hydrolethalus. Usually the characteristic internal renal malformations and the presence of encephalocele allow the diagnosis of Meckel–Gruber and the brain findings differentiate Hydrolethalus. Another syndrome termed Holoprosencephaly Polydactyly syndrome is incompletely understood. It is not caused by known Holoprosencephaly gene mutations (286), but may be an autosomal recessive condition. A severe presentation of Smith-Lemli-Opitz syndrome also overlaps significantly with T13.

#### 43.5.5 Trisomy 13 Mosaicism

Like other mosaic autosomal trisomy phenotypes, mosaic T13 is variable, from normality to full T13 syndrome (287,288). As in other trisomies, there is little correlation between the percentage of mosaicism and the clinical phenotype (289). Skin pigment abnormalities such as hypomelanosis of Ito or the relatively specific phylloid hypomelanosis (defined as pigmentary mosaicism characterized by congenital hypochromic macules resembling a floral ornament with various elements such as round or oval patches, macules resembling the asymmetrical leaves of a begonia, or oblong lesions) are good clues (290). Mosaicism for T13 is most often a result of a meiosis I error followed by trisomy rescue (291). Overall, mosaicism for T13 is quite rare, with only 49 cases being reported in the most recent published review (292).

#### 43.5.6 Cytogenetics of Trisomy 13 Syndrome

Like trisomies 21 and 18, T13 is a maternal age-related autosomal trisomy, with the rate at prenatal diagnosis or birth rising until 43 years and then leveling off. About 75% of spontaneous abortuses and the same proportion of live-born infants with T13 syndrome have an extra, unattached chromosome 13. SNP arrays and DNA marker studies have revealed that the extra chromosome

is maternally derived in about 90% of these cases (292). Most of the time the stage of nondisjunction is maternal meiosis I but in the recent study of Bugge and colleagues (293) just under half the trisomies were meiosis II errors, a much higher rate than that seen in the other acrocentric chromosomes.

In about 20% of cases with T13 syndrome, the extra chromosome 13 is attached to another chromosome, usually a rob(13q14q), with the greater proportion arising from new mutations. This translocation carries a significant risk of unbalanced gametes and the segregation in males reveals more abnormal spermatozoa than previously predicted (294). In addition, in paternal carriers there is a risk for paternal uniparental disomy (UPD) 14 with a distinct clinical phenotype consisting of characteristic “coat hanger” rib findings, intellectual disability and obesity (295,296).

The majority of (13q13q) cases arise *de novo* and are isochromosomes arising from prezygotic fusion of long-arm sister chromatids. Barring effects of isozygosity for a single gene mutation, UPD 13 is expected to be harmless.

#### 43.5.7 Recurrence Risks

As with T18, recurrence of T13 is rare. In a questionnaire and telephone survey of families with trisomies 18 and 13 children, the sibling recurrence risk was less than 1% (248,249). As in DS there appears to be a risk for recurrence that is higher in younger mothers (212,227). The recurrence risk can be for T13 as well as other trisomies. Traditionally the highest risk estimates might be, first, for young mothers less than 30 years who have had an index case with T13; a rounded-up 1% at the time of prenatal diagnosis may be offered as the chance of recurrence of any viable autosomal trisomy. In the case of mothers aged 30–40 years, twice the maternal age-related risk for DS represents the highest risk. For mothers over 40 years, the maternal-age specific risk of occurrence of trisomy is the best estimate. Cytogenetic prenatal diagnosis is customarily offered. A recent study by Engels and colleagues (297) suggests that in translocation carriers the risk is probably somewhat higher than the 1% risk previously estimated. They looked at 101 carriers of a rob 13;14 translocation ascertained in a variety of ways. They found a miscarriage rate of 27%. Three of 42 amniocentesis in this group revealed T13 (7%). Although not addressed in this study the risk for paternal UPD 14 is increased in male carriers.

For male and female carriers of the rob(13q21q) and rob(13q22q), the risk of T13 syndrome is less than 1%, but the risk of DS in pregnancies of the female carrier of rob(13q21q) is 10–15%. For the rob(13q15q) carrier, there is a less than 1% risk for T13, but the significant risk for UPD 15 is notable.

### Biography

Dr Cynthia Curry is a clinical geneticist, Professor of Pediatrics at UCSF San Francisco and adjunct Professor of Pediatrics at Stanford. She practices in Fresno, California, where she is director of a State of California Prenatal Diagnosis Center and Genetic Medicine Central California. She is a graduate of Mt Holyoke College and Yale University School of Medicine. She is trained in pediatrics at the University of Washington and the University of Minnesota. She completed a fellowship in clinical genetics at UCSF. She has served on the American Board of Medical Genetics and on the board of the American Society of Human Genetics. Her research interests include microarray abnormalities, skeletal dysplasias and syndrome delineation.

## Sex-Chromosome Abnormalities

## 44.1 INTRODUCTION

The sex chromosomes X and Y are structurally distinct and subject to different forms of genetic regulation. Despite differences, they are thought to have descended from a common progenitor and during this process, the Y chromosome has become depleted of most genes. A number of genes retain copies on both the X and Y chromosomes, where of many are present in the two pseudoautosomal regions at the termini of the short and long arms of the sex chromosomes. Pairing at meiosis facilitates exchange of information at both pseudoautosomal regions. One X chromosome is inactivated in somatic cells of normal females. The Barr body, a chromatin mass visible in interphase, represents this inactive and late-replicating X. Therefore, the number of Barr bodies is always one less than the total number of X chromosomes per somatic cell. Inactivation is believed to occur early in embryonic life, completing by the end of the first week of development. The maternally and paternally derived X chromosomes are randomly inactivated in female somatic cells. Inactivation is permanent and clonal although new perspectives are constantly being added to our understanding challenging this view (1). These features are the basis of the Lyon hypothesis (2).

Three consequences of X inactivation are dosage compensation, variability of expression in heterozygotes, and mosaicism. X inactivation transcriptionally silences most, but not all, of the genes on one of the two Xs in females. In women, with two X chromosomes, random X inactivation takes place (3). This is a process that goes on in every single cell in the body. The process is governed by the X inactivation center (XIC) and initiated by *XIST*, a gene encoding a long intervening noncoding RNA (lincRNA). The *XIST* gene is located close to the centromere on the long arm of the X chromosome (4), and it orchestrates repressive histone modifications (recruiting *PRC2*) along the X chromosome leading to inactivation. In the remaining active X chromosome, *PRC2* is titrated away by the product of *TSIX*, which effectively leaves all females as

mosaics for the X chromosome with one of maternal and one of paternal origin. However, a great number of genes that are spread out on the X chromosome escape this X inactivation by unknown mechanisms (3), and dosage compensation takes place, so that expression between males and females are comparable for many genes (5,6). Approximately 65% of genes are fully silenced, while 15% completely escape X inactivation and 20% show variable expression, depending on tissue cell origin (7). LincRNAs are pervasively transcribed in the genome although their role in health and disease is poorly understood (8). Studies of dosage compensation, imprinting and homeotic gene expression suggest that lincRNAs function at the interface between DNA and chromatin remodeling (9–11) with further involvement in reprogramming of chromatin to promote cancer metastasis (12). To date, a range of different interactions has been hypothesized for lincRNAs in transcriptional regulation (9), and they may function both as intact interacting molecules as well as Dicer processed molecules that are chopped into small interfering RNAs that degrade other RNAs. The expression of a given gene may be regulated by another gene or genes, and thus, a gene only expressed on the one X chromosome because of X inactivation may still be reduced in expression in Turner syndrome (TS) if a regulatory gene avoiding X inactivation is missing, as seems to be the case with the biglycan gene (13). Biglycan is a glycosaminoglycan partaking in normal connective tissue function, and a reduced amount of this protein may explain some of the characteristics of TS.

The number and distribution of genes escaping inactivation are the subjects of considerable research. The clinical importance of genes that escape inactivation is uncertain; however, these genes may explain clinical features in sex-chromosome aneuploidy as gene products may be either under- or overexpressed in relation to normal females and males.

Because inactivation is random and occurs early in embryonic development when there are few cells, females

with one X carrying an altered gene, such as Duchenne muscular dystrophy or hemophilia A, have a varying proportion of cells, in which the altered allele is active. As a consequence, they exhibit variable phenotypes. The range can be extreme, from a normal female to one in whom there are significant and potentially severe clinical manifestations of the disorder. In addition, females have two populations of cells, in which one or the other X chromosome is active; in other words, they are mosaic with respect to their X-linked gene expression.

There are exceptions to random inactivation. In almost all individuals with structural abnormalities of the X chromosome, the structurally abnormal X is inactivated, mediating against unbalanced cells and their effect on phenotype. This preferential inactivation means that structural anomalies of the X chromosome are better tolerated than autosomal equivalents and are thus more frequently observed. Nonrandom inactivation is also the rule in X-autosome translocations. If the translocation is balanced, the normal X is preferentially inactivated, and the two parts of the translocated chromosome remain active, reflecting selection against a situation that would silence autosomal genes. In an unbalanced translocation, only the product carrying the XIC is present and this chromosome is invariably inactivated, the normal X being always active. These nonrandom events minimize the likelihood that a particular chromosomal defect will have clinical consequences.

Sex-chromosome abnormalities include monosomy X, polysomy of X and/or Y, structural changes in the X and Y chromosomes, and mosaicism. Early data on the health and developmental prognosis of these individuals were extremely biased by the method of ascertainment. Long-term prospective studies of unselected newborns and recent epidemiological studies have provided a more accurate natural history emphasizing not only how many aspects of these phenotypes fall within the range of “normal,” but also that morbidity and mortality are increased for all sex-chromosome abnormalities.

The parental origin of nondisjunction of the sex chromosomes has been studied. In XXY males, the origin of the extra X is equally likely to be maternal or paternal. In XXX females, the extra X is maternal in more than 90% of cases, reflecting a preponderance of maternal meiotic errors (14). In monosomy X, the paternal X is lost in approximately 80% of individuals. Research continues to explore a parent of origin effect (imprinting), particularly in monosomy X. One study found evidence of superior verbal and higher order executive function skills, which mediate social interactions, when the retained X was paternal (15,16), while others have not been able to replicate this finding (17).

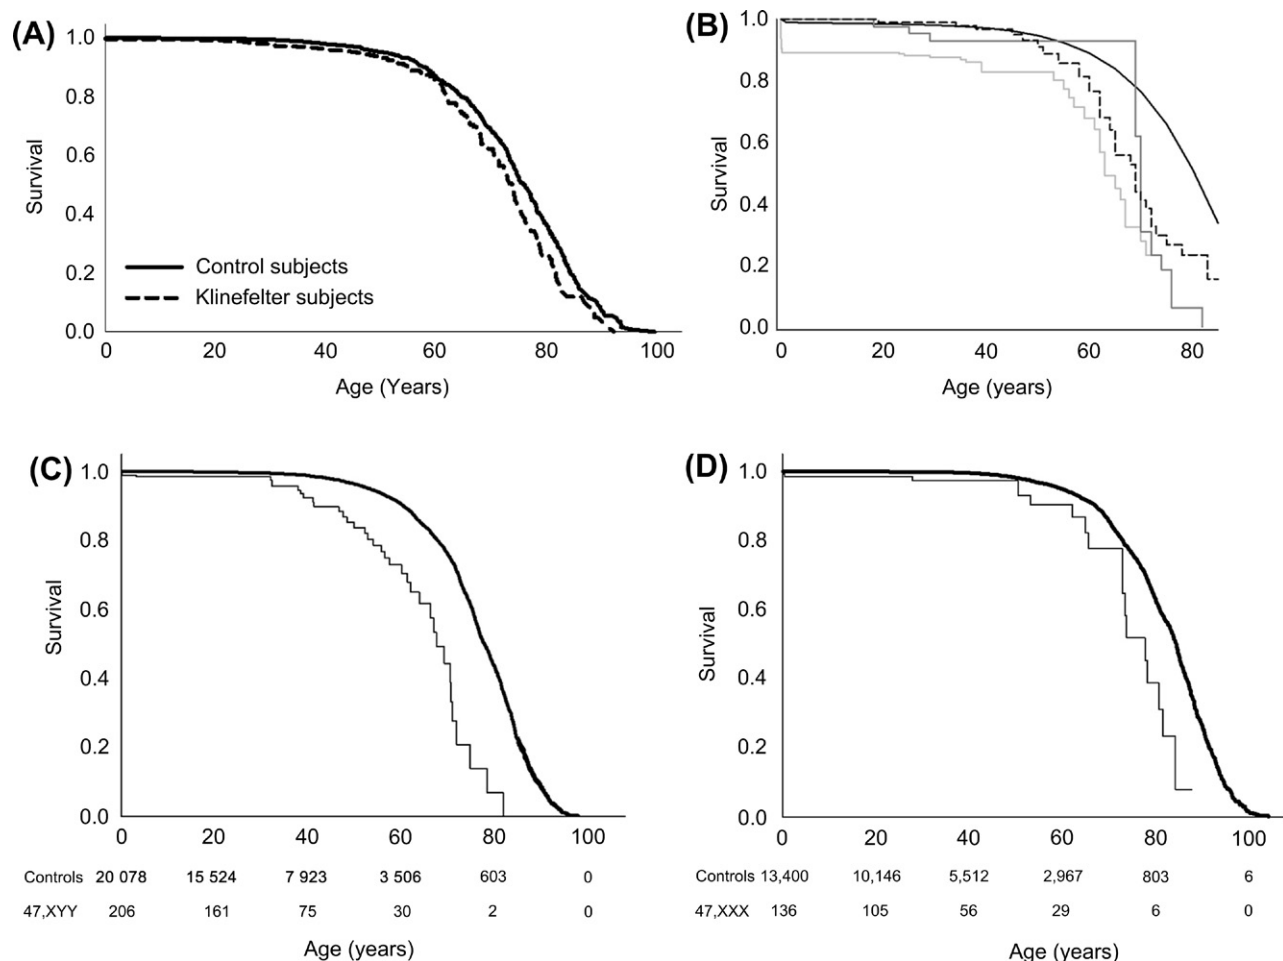

The risk of offspring with polysomy X rises with increasing maternal age, whereas mothers of offspring with monosomy X are predominantly younger than average (18). A sex-chromosome abnormality was diagnosed in about 1 in 250 amniocenteses performed on women

35 years of age and older. These abnormalities may be more common in chorionic villous sampling (CVS). This rate is higher than that found at term, suggesting that there is significant loss of these fetuses in the latter half of pregnancy (19). Since the advent of widespread maternal serum screening with  $\alpha$ -fetoprotein, estriol, and human chorionic gonadotropin (HCG), abnormal analytes may be detected in the presence of sex-chromosome aneuploidy, particularly 45,X (20).

## 44.2 THE EPIDEMIOLOGY OF SEX-CHROMOSOME ABNORMALITIES

Our estimates of the prevalence and incidence of sex-chromosome abnormalities are based on rather old studies dating back to the 1960s–1980s (21–28). These studies provided estimates for the prevalence of TS, Klinefelter syndrome (KS), 47,XXX syndrome and 47,XYY syndrome. Accordingly, we expect about 50 per 100,000 females with TS, 150 per 100,000 males with KS, 85 per 100,000 females with 47,XXX and 100 per 100,000 males with 47,XYY. It has even been suggested that the prevalence of KS is increasing (29). However, studies show significant delay in diagnosis or even nondiagnosis for all these four syndromes. It is estimated that only about 65% of TS, 25% of KS, 12% of 47,XXX and 14% of 47,XYY patients are diagnosed (30–34). The prevalence of prenatally detected cases with sex-chromosome trisomies is also low and a European study shows a termination of pregnancy rate of 36% (35). Thus, current clinical literature is, of course, based on diagnosed individuals and may therefore be biased by selection, especially, for example, if nondiagnosed individuals are less stigmatized or perhaps even more stigmatized suffering an early demise and thus remain undiagnosed. Furthermore, such figures highlight problems related to diagnosis and emphasize that the current diagnostic approach, which is most often by clinical indication, is not efficient in identifying individuals with sex-chromosome abnormalities (36). Work is underway to advance the use of high throughput methods for the diagnosis of sex-chromosome abnormalities (37).

Mortality is increased in all major sex-chromosome abnormalities (31,33,34,38–43), with hazard rates (or standardized mortality rates) ranging from 1.4 to 1.6 for KS, 2.1 to 2.5 for 47,XXX, 1.9 to 3.6 for 47,XYY and 2.9 to 4.2 for TS (Figure 44-1). The specific causes for the increased mortality rates are described below. Rates of morbidity have been studied in TS and KS and have been found to be increased (44,45). In TS, this increase is closely linked to a range of conditions known from clinical studies to be more prevalent (see Section 44.3.1). In KS, there is an increased risk of being admitted to hospital for virtually any disease, including psychiatric disorders and congenital malformations (45), which is difficult to attribute specifically to the chromosome aberrations or the known consequences of the condition—i.e.

**FIGURE 44-1** (A) Survival of KS subjects vs control subjects (hazard ratio, 1.40; 95% CI, 1.13–1.74;  $P < 0.002$ ). KS subjects lost 2.1 years (95% CI, 0.3–3.9 year; median survival) compared with control subjects (179). (B) Kaplan–Meier plots of cumulated mortality in the general population (black line), females with 45,X (light-gray line), females with an isochromosome Xq (dark-gray line), and females with all other karyotypes associated with TS (dashed-black line) (31). (C) Kaplan–Meier survival graphs in 47,XYY compared to an age-matched male background population. Solid line is for controls, and thin line is for persons. Survival is significantly lower in 47,XYY persons, log-rank  $P < 0.0001$ . Number of persons and controls are indicated below the figure (34). (D) Survival graph of all women with a 47,XXX karyotype (thin line) and their age- and gender-matched controls (solid line). Log-rank:  $P < 0.0001$ . Numbers of 47,XXX persons and controls are indicated below the figure (33).

hypogonadism, infertility and cognitive problems. The gene-dose effect may be a plausible cause of the congenital malformations and testicular failure and may also account for the increased risk of delayed speech, learning difficulties, and psychiatric diseases. Disturbed lateralization of the brain hemispheres has been associated with aneuploid number of X chromosomes and increased risk of dyslexia, disturbed verbal execution, and schizophrenia (46). There are no studies describing morbidity in 47,XXX and 47,XYY syndromes.

### 44.3 TURNER SYNDROME

A plethora of information has been added and our current understanding of the syndrome is continuously being broadened since the initial description of TS by Ullrich (47) in 1930 and later Turner in 1938 (48).

Others, such as the Russian physician Seresevskij, had described the syndrome before this time (49). The syndrome only affects females and medical care must include close collaboration between specialties such as genetics, embryology, pediatrics, gynecology and obstetrics, endocrinology, cardiology, gastroenterology, otorhinology and ophthalmology.

#### 44.3.1 Diagnosis, Genetics and Epidemiology

There are no evidence-based diagnostic criteria for TS. However, certain phenotypic traits coexisting with a spectrum of karyotypes comprise the diagnosis. The generally accepted cardinal physical stigmata include growth retardation with reduced adult height, gonadal insufficiency, and infertility (50). The genetic background of TS

is highly variable but includes complete or partial absence of a sex chromosome (the X or Y chromosomes). Mosaicism of two or more cell lines can be present with cutoff levels for low-grade mosaicism yet to be defined because some report 5% while others report 20% diagnostic levels (51,52). The spectrum of karyotypes results from sex-chromosome nondisjunction, events which may occur in the first or second division of meiosis during spermatogenesis or oogenesis or during later mitotic division in early embryonic development.

The classical karyotype 45,X accounts for 50% of cases with the remainder composed of mosaic karyotypes, karyotypes with an isochromosome of X—for example, i(Xq) or i(Xp)—or karyotypes with an entire or a part of Y chromosome (Table 44-1) (44). The genetic basis for the phenotype of TS is being unraveled. This includes improved knowledge of the functions of the *SHOX* gene, which is located on the X chromosome. Haploinsufficiency of *SHOX* explains growth retardation, changes in bone morphology, sensorineural deafness and other features. Additional genes are more than likely to be involved in the pathogenesis of TS but await discovery.

Prenatal prevalence of the syndrome is much higher than the postnatal prevalence, because of increased intrauterine mortality and induced abortions (53,54). Generally, the initial prenatal diagnosis of TS relies on an ultrasound scan focused on congenital malformations around week 19, which is neither sensitive nor specific enough to accurately establish the diagnosis of TS, and thus prenatal diagnosis of TS may not always be correct. Therefore, precise prenatal diagnosis must include high-resolution ultrasound scan, fetal echocardiography and other advanced imaging modalities, such as magnetic resonance imaging (MRI), augment fetal karyotyping. Following confirmation of diagnosis, most fetuses with TS are legally aborted. An European multicentre study found an induced abortion rate of 66%,

which confirms previous studies of legal abortion rates of 60–80% (44). However, this is only a fraction of fetuses with TS since <10% of any pregnant population are subjected to invasive methods of prenatal diagnosis and prenatal ultrasound scan only diagnoses fetuses at the most abnormal end of the spectrum of TS phenotypes, such as hydrops or increased nuchal fold (44). Maternal age and low height are risk factors for giving birth to a girl with TS and newborn girls with TS are smaller and shorter for gestational age than the background population (55).

Postnatal diagnoses are made at birth (15%), during teenage years (26%) or in adulthood (38%) with the remainder being diagnosed during childhood (36). The key to diagnosis is lymphedema in 97% during infancy and short stature in 82% in childhood and adolescence (36). Unfortunately, delay in diagnosing girls and adolescents is substantial (31).

Morbidity is considerably increased in TS. In a study of all females diagnosed with TS and compared with the general population of women, the relative risk (RR) of an endocrine diagnosis in TS patients is increased to 4.9 when compared with the female background population, with specific increases in hypothyroidism (RR 5.8), type 1 diabetes mellitus (T1DM) (RR 11.6) and type 2 diabetes mellitus (T2DM) (RR 4.4). The risk of ischemic heart disease and arteriosclerosis (RR 2.1), hypertension (RR 2.9), and vascular disease of the brain (RR 2.7) was also increased. Furthermore, the risk of other conditions such as cirrhosis of the liver (RR 5.7), osteoporosis (RR 10.1) and fractures (RR 2.16) was also increased, as were the risks for congenital malformations of the heart, the urinary system and the face, ears and neck. The risk for all cancers was comparable to other women (44). In addition to morbidity, mortality is increased in TS. In a British cohort study, the RR of premature death was increased to 4.2 (41) because of disease in the nervous, digestive, cardiovascular (CV), respiratory and genitourinary systems. Death due to cancer was lower than expected, corroborating morbidity studies. In Danish patients, the patterns of mortality were comparable, and there were important differences between patients with 45,X and those girls and women with an isochromosome, who had a fourfold increased mortality, whereas patients with other karyotypes only had a twofold increase in mortality (31).

### 44.3.2 TS and the CV System

Diseases of the heart and vasculature account for 50% of excess mortality in TS (40). A number of left-sided CV malformations occur with increased frequency. Elongated transverse aortic arch and aortic coarctation are seen in 50% and 4–14% of TS women, respectively (56,57). Bicuspid aortic valve occurs in 13–43% of TS patients versus 1–2% of general population (58) (Figure 44-2). Less commonly right-sided malformations, such as persistent left vena cava superior and partial anomalous venous

**TABLE 44-1** Distribution of Prenatal and Postnatal Turner Syndrome Karyotypes

Karyotype	Prenatal	Postnatal
45,X	134 (64%)	162 (47%)
45,X/46,XX	45 (22%)	59 (17%)
45,X/46,X,i(Xq) <sup>a</sup> ; 46,X,i(Xq); 45,X/46,X,i(Xq)/47,X, i(Xq),i(Xq) etc.	9 (4%)	41 (12%)
45,X/46,X,del(X); 46,X,del(X)	15 (7%)	27 (8%)

45,X/46,X,r(X)	1 (<1%)	20 (6%)
45,X/46,XY	—	10 (3%)
Others with Y material	—	11 (3%)
	209 (100%)	346 (100%)

<sup>a</sup>i(Xq) = isochromosome X(q) (106).

return, are encountered (56). These congenital heart defects may cosegregate, and in a small proportion, the cardiac phenotype is more severe in its affection of the left ventricle and the thoracic aorta—the hypoplastic left heart syndrome.

Some of the congenital CV defects call for early and potentially life-saving high-risk CV intervention, thereby contributing to both increased mortality in infancy and later on in life from complications of the congenital abnormalities disease and the necessary interventions (31). Other defects present less acutely, with symptoms associated with late life morbidity. Then again, some remain subclinical throughout the entire lifetime with an unresolved role to the pattern of morbidity and mortality in TS.

More than 30% of young girls and adolescents and 50% of adults with TS are mildly hypertensive on 24-h ambulatory measurements (59–63). Additionally, 50% have abnormal circadian blood pressure profiles (60,61,64). Though the pathological nature underlying hypertension in TS remains unknown, it is uniformly accepted that hypertension and sympathovagal dysfunction with nocturnal “nondipping” confers a high risk of future CV events, as also epidemiologically documented in TS (31). The presence of these risk factors adds to the other adverse indices of CV risk in TS: increased carotid intima thickness (63), propensity toward glucose intolerance and type 2 diabetes (61,65), nonalcoholic steatohepatitis (66–68), discordant lipid profile (69,70), estrogen deficiency and unfavorable body composition (71).

Beyond congenital cardiac malformations such as the bicuspid aortic valve and aortic coarctation, hypertension is thought to be a major contributing factor (62) to an extremely high incidence of aortic dissection of 40 per 100,000 TS syndrome years versus 6 per 100,000 general population years (72). Aortic dissection strikes TS patients at a median age of 35 years as opposed to 71 years in the general population (72). Normally, dilatation of the ascending thoracic aorta precedes dissection and rupture, and an abnormal aortic caliber is seen in up to 42% of nonselected adult patients with TS (73,74), increasing with age (75). Aortic caliber correlates with systolic blood pressure, but surprisingly, not with vascular atherosclerotic indices such as aortic stiffness or plasma lipids (62). An intrinsic arterial wall defect is highly likely as part of the generalized vasculopathy in TS, similar to the bicuspid aortic valve syndrome (63,76) (see Chapter 46).

Subclinical impairment of diastolic function associated with increased left-atrial dimensions is seen even in normotensive and strictly metabolically controlled TS (38). Additionally, the adverse prognostic marker N-terminal pro-brain natriuretic peptide (BNP) is elevated in the absence of symptoms of cardiac failure and without systolic dysfunction (64). Adding further prognostic burden to the CV phenotype, prolongation of the QTc interval is seen in 30% of girls, adolescents and adults with TS (77,78), a condition accepted as an independent predictor of sudden CV death.

Premature ovarian failure with estrogen deficiency is the most prevalent CV risk factor in TS. How premature

**FIGURE 44-2** Illustration of the occurrence of bicuspid aortic valves, aortic coarctation and the place in the ascending aorta where dissection often occurs. Furthermore, illustration of the frequent occurrence of hypertension.

estrogen deficiency impacts CV prognosis is unclear although young age at menopause in other populations confers a more adverse risk profile. Evidence confirming earlier observational findings of estrogen-derived cardioprotection is supported by animal and human studies showing anti-inflammatory, antioxidant and lipid-lowering effects with modification of disruptive vascular processes. Conversely, opposing such protective effects is the potential for the induction of myocardial hypertrophy, venous thromboembolic events, and dysrhythmia (79). In interventional studies, estrogen replacement therapy failed to reduce the risk of CV disease in primary and secondary prophylaxis of atherosclerosis in postmenopausal women. The potential for alleviation of adverse risk in premature ovarian failure has not been investigated. However, evidence is mounting to a beneficial effect of estrogen substitution on CV risk with the early introduction states of deficiency of female sex steroids—the so-called “timing hypothesis” (79).

Collectively, congenital and acquired CV disease occurs on a backdrop of endocrine deficits, resulting in a highly variable cardiac phenotype in TS where risk assessment and reduction is difficult. Therefore, all girls and women with TS should be regarded as having increased risk of CV events (80), and TS girls and women require a thorough baseline delineation of cardiac phenotype and regular follow-up by cardiologists trained in congenital heart disease (81). Depending on the presentations, examination should include an electrocardiogram, 24-h ambulatory blood pressure, echocardiography and MRI (81).

### 44.3.3 Ovarian Insufficiency and Hormone Replacement Therapy

Premature ovarian failure is the common denominator in most patients with TS (82). Early ovarian demise presents and estrogen insufficiency ensues. Ovarian germ-cell count is normal until week 18 of gestation, after which accelerated degeneration takes place. High levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are present in early childhood (2–5 years) and after the time of normal puberty onset (11–12 years) (83,84). During the time of normal puberty, the levels of FSH and LH increase to menopausal levels; however, many untreated girls show signs of puberty and/or have regular periods for a varying length of time (85). Ovarian follicles may be present in 45,X patients even in 12–19-year-olds (86), probably because of unrecognized mosaicism for a 46,XX cell line. Anti-Müllerian hormone (AMH) and inhibin B are emerging as possible markers of ovarian function (87,88). Understanding the processes in early follicular apoptosis in TS may, in the future, lead to a treatment sparing the follicles and maintaining fertility.

Timing of sex hormone replacement therapy (HRT) should allow onset of puberty at the same time as peers of the patient to avoid social problems secondary to delayed physical and psychological development. This also allows

optimal bone mineralization to take place. In most normal girls, puberty starts around 12 years of age. Since 30% of girls with TS undergo some spontaneous pubertal development and 2–5% have spontaneous menses with a small potential to achieve pregnancy without medical intervention (85,89), signs of puberty should be looked for before starting estrogen therapy. When FSH and LH are clearly elevated, AMH and inhibin B are low, and clinical signs of puberty lacking, pubertal induction should be started, although always considering individual circumstances. To induce pubertal development, the dosing and timing of estrogen therapy should aim at mimicking normal pubertal development. Doses should be individualized starting with very low doses of estrogen as monotherapy, either orally or percutaneously (90,91). The treatment should be monitored by the development of secondary sex characteristics (Tanner staging), serum LH and FSH, bone maturation or uterine volume. A gestagen is added when breakthrough bleeding occurs. Currently, it is not clear which gestagen is the most advantageous.

Estrogen therapy should always be coordinated with the use of growth hormone (GH). These initiatives should be individualized in order to optimize and coordinate growth and pubertal development. When growth is a priority, delaying estrogen therapy is an option to avoid compromising adult height. However, recent growth-promoting trials have documented that physiological timing of estrogen therapy does not compromise final height, when GH therapy is started early and dose is increased stepwise (92). HRT is a cornerstone of therapy of TS to optimize feminization and bone mineralization, and to enhance motor speed and verbal and nonverbal memory and processing. Females with TS present with a particular neurocognitive profile, with impaired performance on motor tasks, impaired visual-spatial ability, but normal verbal skills (93). The deficits in cognition are likely to be caused by haploinsufficiency of X-linked genes that normally escape X-inactivation, but these putative genes await further elucidation.

Infertility is rated as the most prominent problem in adult women with TS (94). Oocyte donation is possible in many countries and fertility preservation is an emerging option. The most recent studies show good results, or at least comparable to oocyte donation in other infertile patients. However, better preparation of the uterus for implantation (assessed by uterine size and endometrial thickness) with prolonged treatment with high daily doses of estradiol (4–6 mg or up to 8 mg of 17 $\beta$ -estradiol) may improve results in TS. Importantly, it is a high-risk endeavor for a TS woman to go through pregnancy, especially in relation with the CV system but also secondary to endocrine features. A high rate of maternal complications has been reported in some studies (95,96) although a recent study reported a much lower rate of complications after sufficient CV screening before pregnancy (89).

Androgen insufficiency is present (97), and one needs to evaluate the possible benefits of androgen substitution in TS.

During adulthood, it is important to continue HRT, even though a number of issues such as dose during the different ages, administration route, type of estrogen and type of gestagen are unresolved. Female hypogonadism is related to a number of other conditions, and HRT may reduce or even completely alleviate the risk of these. Currently, new studies indicate that the traditional dose of 2 mg of estradiol used in TS and other conditions of premature ovarian failure may be too low for reducing occlusive vascular risks and for normal growth of the uterus (98,99). The presently available evidence on different routes of administration in TS has not clearly demonstrated superiority of any particular route (61,66,100); newer studies point toward advantages with transdermal or subcutaneous application (101–103) but additional studies are needed to fully resolve this issue. A few studies have compared the contraceptive pill with physiological 17 $\beta$ -estradiol and a gestagen and they suggest that the contraceptive pill should not be used in the long-term treatment of TS (104,105).

#### 44.3.4 Decreased Stature in TS

Short stature is the cardinal finding in girls with TS affecting 95–99% (106). Growth retardation is already present in utero with birth weight approximately 1 SD below expected. Growth remains retarded in infancy and childhood, where height is 2 SD below normal and, because of absent pubertal growth spurt, the heights encountered at age 14 are 4 SD below expected if GH treatment has not been initiated (107). Overall, the growth phase is prolonged (if puberty is not induced) achieving a spontaneous final height of almost 3 SD or about 20 cm below normal height.

Part of the explanation of the small final height relates to the action of the *SHOX* gene located to the PAR1 region of the X and Y chromosomes; haploinsufficiency of *SHOX* leads to reduced final height as documented in Leri–Weill dyschondrosteosis. However, the height difference is only about 50–75% of what is seen in TS. Therefore, *SHOX* deficiency can only explain part of the height deficit in TS (108). BNP and fibroblast growth factor receptor 3 (FGFR3) are transcriptional targets of *SHOX* and present alongside at the growth plate in proliferative chondrocytes (109). Whether the lack of *SHOX*-induced BNP and FGFR3 is involved in CV malformations and diseases in TS remains to be elucidated.

Even though GH concentrations in TS have been found normal by some and reduced by others, it is generally concluded that girls with TS have a growth deficiency with reduced sensitivity to GH rather than a GH deficiency. GH treatment can increase growth velocity and final height. The effect is dose-dependent, and normalization of final height has been shown to be obtainable with high doses (92,110). In the only randomized controlled study, using GH treatment (0.3 mg/kg/week) or placebo, a significant increase in final height of 7.2 cm (CI: 6.0–8.0) was seen, with HRT started at age 13 (110).

If TS diagnosis is made early (before 1–2 years of age), treatment with GH should commence at an early stage. In a randomized controlled open-label study that administered GH to 9-months–4-year-old girls, growth retardation was corrected with growth catch up, bringing 93% of the toddlers back in the normal height range within 2 years. The placebo group had progressive growth failure (111).

Besides effects on growth and final height, GH treatment also has beneficial effects on body composition, with reduced fat mass and an increase in lean body mass. Concerns about the effect of GH on the heart has arisen from evidence that left ventricular hypertrophy is found in acromegalic patients with high levels of GH. A Dutch study showed no signs of left ventricular hypertrophy and no increase in blood pressure in TS girls undergoing 7 years of GH treatment (112).

#### 44.3.5 Endocrine and Metabolic Disorders

**44.3.5.1 Glucose Metabolism and Diabetes.** Both T1DM and T2DM occur more frequently in women with TS. Impaired glucose tolerance (IGT) has been reported in both girls and women with TS. An epidemiological study including 594 TS women found an increased RR of both T1DM and T2DM (44).

Generally, fasting glucose levels are not significantly different from controls, but fasting hyperinsulinemia has been documented and during an oral glucose tolerance test (OGTT), IGT has been found in 25–78% (61,65) of adult TS. In addition to higher glucose levels, the insulin response is increased and some have found a delayed insulin peak during an OGTT. The impaired glucose homeostasis seems to be explained by a decreased insulin sensitivity as well as a reduced “first phase insulin response,” which could be viewed as an inappropriately low  $\beta$ -cell response (61,65). Body composition is distinctly altered in TS with increased BMI, as well as decreased muscle mass, increased total fat mass and visceral fat mass. A more sedentary lifestyle and decreased VO<sub>2</sub>max is also found in this population. All factors contribute to the risk of developing reduced insulin sensitivity and diabetes (71,113).

Appropriate HRT in TS also seems to be important for glucose homeostasis even though the findings in TS are not uniform. HRT reduced fasting glucose and fasting insulin (114), and while not improving insulin sensitivity, fat-free mass and physical fitness did increase—both latter factors improve glucose homeostasis. In contrast to this, more subjects were found to have IGT during an OGTT while receiving HRT (61). On balance, HRT may slightly improve glycemic control in TS.

Insulin levels, both fasting and as an OGTT response, increase during GH treatment (115). The insulin levels decrease after termination of GH but they remain higher than pretreatment levels (92). GH therapy reduces insulin sensitivity during the first 6–12 months of treatment where after it stabilizes, but this effect subsides with

cessation of treatment (92). This stabilization could be due to changes in body composition with an increase in lean body mass and decrease in fat mass. The proportion of TS patients with IGT does not seem to increase significantly during treatment, and HbA<sub>1c</sub> remains unchanged or even decreases during GH therapy. While most of the effects on the glucose metabolism seem to reverse after cessation of GH treatment, the long-term effects of the GH-induced hyperinsulinism and insulin resistance are not known.

With widespread abnormalities in the glucose homeostasis and an increased risk of T1DM and T2DM, there is a need for attention to the increased risk of impaired glucose homeostasis and diabetes in TS. Recommendations for diagnosis and treatment of diabetes should adhere to general population guidelines. However, yearly screening of fasting glucose should be performed.

**44.3.5.2 Gastroenterology and Hepatology.** Increased concentrations of liver enzymes, especially alkaline phosphatase, alanine/aspartate aminotransferase and  $\gamma$ -glutamyl transferase (markers of hepatic cell lesion or turnover), are frequent in TS. Bilirubin (excretion marker) and coagulation parameters (production markers) are, in most cases, within the normal range. In a liver biopsy study in 27 women with TS who were biopsied because of persistently elevated liver serology (116), multiple abnormalities were found. These included marked nodular regenerative hyperplasia, multiple focal nodular hyperplasia, and cirrhosis, associated, in some, with obliterative portal venopathy. Other patients showed more moderate changes, including portal fibrosis, inflammatory infiltrates and nonalcoholic fatty liver disease. The authors conclude that the main causes of liver abnormalities in TS are vascular disorders thought to be congenital in origin, and nonalcoholic fatty liver disease, without signs of liver toxicity from concomitant estrogen therapy. This study is cornerstone for several reasons: it is the largest, it includes liver biopsies as well as thorough evaluation of other causes of liver disease (excluding viral, autoimmune and alcoholic causes), and it excludes HRT as causative to the liver abnormalities. In keeping with this, HRT normalizes measures of liver function and dynamic liver tests are normal and not affected by HRT in TS (68).

Inflammatory bowel disease also appears to be more frequent in TS (2–3%) and, especially, should be suspected in girls not responding to GH therapy. Celiac disease is present in 8% of patients (117,118) and because this may cause additional growth stunting, it should always and repeatedly be excluded. The general guidelines should be followed for these enteric diseases.

**44.3.5.3 Diseases of the Bone.** Peak bone mass depends on a number of factors, such as genetic background, nutrition, physical activity, local growth factors and a spectrum of hormones. Estradiol secretion is clearly deficient in childhood and adolescence. Children and younger and middle-aged adult patients with

TS have low bone mineral density (BMD), and studies show that fracture risk is increased (44,119,120). HRT is crucial to induce maximal peak bone mass in adolescents and young adults and to avoid a rapid decrease in BMD in adulthood (121). This is supported by longitudinal studies of estrogen-deficient and estrogen-replete adolescents with TS. Furthermore, patients with spontaneous menstruation have normal BMD, whereas absent menarche associates with a reduced BMD. A 3-year longitudinal study of 21 women with TS (age 20–40), with iliac crest biopsies before and 3 years after treatment with HRT, showed marked effects of estrogen on bone. Treatment consisted of estradiol implants (and an oral gestagen cyclically) (102) resulting in estradiol levels comparable to levels in premenopausal women, and considerably higher than levels achieved with regimens used hitherto (estradiol 2 mg orally or equivalent transdermal doses). Bone biopsies pointed toward an anabolic effect on the skeleton of estradiol in young TS (102). Furthermore, GH may improve BMD. In a recent 7-year study with GH treatment given at three different doses, BMD increased in a dose-dependent manner. However, estrogen was added after 4 years of GH treatment, and it is difficult to ascertain the individual effects of GH and estrogen in this study (122).

No very long-term studies (both follow-up and intervention studies) of the effect of estradiol have been published but 5 years of appropriate HRT maintains BMD in adulthood (123). There is a definite need for such studies to determine the ideal treatment regimen during adolescence in order to achieve two goals: attaining maximal peak bone mass and maintaining BMD without compromising adult height; and, with appropriate timing of pubertal induction. The optimal dosage of estrogen during adult life is also yet to be determined.

**44.3.5.4 Thyroid Disorders.** Thyroid disease is common in TS. Hypothyroidism is frequent and thyroid antibody formation even more so, with as many as 30% TS patients eventually developing manifest hypothyroidism. Correspondingly, a recent study showed a considerable increase in new cases with hypothyroidism during a 5-year follow-up period (124). It remains an enigma why so many TS patients suffer from diseases related to autoimmunity, and the basis for this grossly increased risk in TS (also including celiac disease, and diabetes (see Section 44.3.5.1)) is unaccounted for. A genetic basis seems probable although undocumented. GH treatment does not increase the frequency of autoantibodies. The treatment of hypothyroidism follows normal guidelines.

**44.3.5.5 Renal and Auditory System.** Structural anomalies of the urinary tract are frequent, but rarely give rise to problems (125) and are apparent on ultrasound.

Middle-ear infection is extremely frequent, especially in the first years of life and often amount to considerable morbidity (126). Some girls with TS already experience social hearing problems due to sensorineural hearing loss during teenage years, which very often leads to the use

of hearing aids (126,127). There are estrogen receptors in the inner ear and estrogen deficiency during childhood and adolescence may be involved in pathogenesis of the accelerated early presbycusis often seen in TS (127,128).

#### 44.3.6 Intelligence, Personality, and Behavior

Most females with TS have normal intelligence, and usually good verbal abilities. In one series of females with TS, including all karyotypes, mental retardation was diagnosed in approximately 10% (129), although this figure may well be too high. Intellectual handicap and karyotype and marker chromosomes derived from an X chromosome correlate. The group with the next highest prevalence of mental retardation (30%) had a ring (X) in their karyotype.

Specific learning disabilities are common, and a TS neurocognitive and psychosocial phenotype has been described. This profile includes impaired visual-spatial processing, social cognition, nonverbal problem solving, and psychomotor deficits (130). When school difficulties are appreciated, a full developmental assessment should be carried out and an individualized education program prepared. Difficulties may arise with attention, maturity, and social skills. Although overall psychosocial adjustment is good, there may be a risk for some social or adjustment problems, particularly with respect to social maturity, relationships, and self-esteem (130). Many girls with TS display immature behavior in comparison with their peers and experience particular isolation in adolescence.

They are at an older age than their peers when they begin dating, leave home, and marry (131,132). Adults also have fewer social contacts, but most do not perceive this as a problem and express satisfaction with employment and social life (131). Adult females with TS achieve similar educational levels as females in general (133) and rate their quality of life similar to matched controls (133–135).

The risk of psychiatric disease, including major reactive depression, affective disorder, psychosis, eating disorders, substance abuse, and obsessive-compulsive disorder, is as high as 10%, which is likely increased above the risk in the general population (136,137).

#### 44.3.7 Conclusions

Patients with TS need comprehensive care preferably from a multidisciplinary team, which can best be practiced from an outpatient clinic with centralized care enabling special emphasis on TS. Glucose metabolism, weight, thyroid function, bone metabolism, blood pressure, liver function, and CV status should be regularly assessed (Box 44-1). Estrogen deficiency should be treated, preferably with natural estrogens and a gestagen, and GH should be commenced early in life.

Importantly, knowledge concerning TS is still limited. There is a large deficit in our understanding of the syndrome with a hope to improve patient outcome through not only

a specialized multidisciplinary clinical approach but also a continuous effort to span disciplines in future research.

#### 44.3.8 45,X/46,XY Mosaicism

Substantial variation in the phenotype associated with 45,X/46,XY mosaicism exists, and much depends on whether the diagnosis is made postnatally, or, fortuitously, prenatally. In the latter circumstance, 90–95% of babies have a normal male phenotype at delivery (138,139). These boys have an increased risk of abnormal gonadal histology. Few prospective data are available on pubertal development, fertility, risk of testicular failure, and likelihood of gonadoblastomas, which is increased in comparison of TS patients with Y chromosome cell lines (140–142). When this diagnosis is made prenatally, detailed ultrasound evaluation will help to identify the minority with ambiguous genitalia and thus facilitate counseling regarding the natural history and prognosis (143). There does not appear to be any correlation between the phenotype and the proportion of cells with 45,X in lymphocyte or fibroblast studies.

When diagnosis of 45,X/46,XY is made postnatally, it is generally because of an abnormal phenotype; however, rare normal males have been identified. The most common presentation is TS, and both females and males with a 45,X/46,XY karyotype show poor growth and seem to benefit from GH treatment to achieve a normal growth

pattern (144). Less frequently, this karyotype is found in the investigation of male pseudohermaphroditism or mixed gonadal dysgenesis, with hypospadias, cryptorchidism, rudimentary phallus, urogenital sinus, or, rarely, true hermaphroditism (139). Associated mental retardation has been described but is unusual. Some apparently normal males, with normal genitalia, have been ascertained because of infertility, with abnormal sperm number or morphology. Some have found an increased risk of sex chromosomal and autosomal aneuploidy in sperm (145), while others have rates of aneuploidy similar to other patients with oligospermia (146).

#### 44.3.9 X;Y Translocations

X;Y translocations in humans are the result of abnormal male meiotic recombination. Translocations involving the X and Y chromosomes generally involve break points in Xp22 and Yq11, producing partial monosomy of Xp with the addition of Yq material. The normal two-copy complement of Xcen-Xq11, a putative TS critical interval, is present. The sex-determining region Y (SRY) is most often absent, so the individual with this translocation is usually a woman with normal intelligence and fertility but short stature. The latter feature likely reflects the absence of SHOX in the pseudoautosomal regions of Xp and Yp, but this can rarely be offset by the presence of GCY (a Y chromosome growth control gene), growth-promoting locus on Yq. Women with t(X;Y) may have demonstrable GH deficiency and may benefit from GH administration. A smaller percentage of women with break points proximal to Xp22 have gonadal dysgenesis, infertility, and variable Turner stigmata in addition to short stature.

Less often, the translocation break point is in Yq, and the product retains SRY, but important coding regions of the Y long arm may be deleted. The phenotype is highly variable. These males may have hypogonadism, infertility, dysmorphism, and a degree of cognitive impairment. When the Y chromosome translocation break point is more distal and only heterochromatic long arm material appears to be lost, there may still be submicroscopic loss of euchromatin that can have important clinical consequences. This possibility should be addressed by molecular methods.

### 44.4 KLINEFELTER SYNDROME

KS is the most common sex-chromosome aneuploidy and was first described by Harry F. Klinefelter, Edward C. Reifenstein and Fuller Albright in 1942, when they published nine cases of a syndrome characterized by gynecomastia, azoospermia, hyalinized small testes, elevated levels of FSH and hypogonadism (147). The cause was unknown until 1959 when Jacobs and Strong demonstrated the extra X-chromosome in the karyotype of KS (148).

#### BOX 44-2 Abnormalities Associated with KS and their Tentative Frequencies

Feature	Frequency (%)
Infertility (adults) (152)	>99
Small testes (<4 ml) (152)	>95
Increased gonadotropin levels (152)	>95
Azoospermia (adults) (152)	>95
Learning disabilities (children) (151)	>75
Decreased testosterone levels (152)	63–85
Decreased facial hair (adults) (152)	60–80
Decreased pubic hair (adults) (152)	30–60
Gynecomastia (children) (151,168)	38–75
Delay of speech development (children) (151)	40–?
Increased height (prepubertal) (151)	30–?
Abdominal adiposity (adults) (175)	~50
Metabolic syndrome (adults) (175)	46
Osteopenia (adults) (194)	~40
Type 2 diabetes (adults) (175)	10–39
Cryptorchism (151,162)	27–37
Decreased penile size (children) (151)	10–25
Psychiatric disturbances (children) (151)	25
Congenital malformations cleft palate, inguinal hernia (204)	~18
Osteoporosis (adults) (194)	10
Mitral valve prolapse (adults) (188)	?–55
Breast cancer (adults) (198,199)	Increased risk (~50-fold)
Mediastinal cancers (children) (197)	Increased risk (~500-fold)
Fractures (43,179)	Increased risk (2–40-fold)

Since then, a number of studies have increased knowledge about the syndrome, especially the chromosome surveys on large number of newborns, with follow-up through childhood and adolescence performed in the 1970s and 1980s (149–151). These studies on unselected newborn individuals with sex-chromosome aberrations focused mainly on development in infancy, childhood and adolescence, leaving the natural history of the adult with KS less well described. The typical man suffering from KS is described as tall, with narrow shoulders, broad hips, sparse body hair, gynecomastia, small testes, androgen deficiency and reduced intelligence (152), but a less well-defined phenotype is present in many patients (153). Typical features are listed in Box 44-2.

#### 44.4.1 Genetic Background

KS is characterized by the presence of one Y chromosome and two or more X chromosomes in a phenotypic male. The most abundant karyotype is 47,XXY but supranumerous X chromosomes and mosaics with mixture of normal cells are not uncommon. In the diagnosed Danish population of KS patients, 90% had the 47,XXY karyotype, while the remaining had rarer karyotypes (Table 44-2), with similar figures found in a British study (43).

**TABLE 44-2 Karyotype Distribution in a Large Series of KS Males**

Karyotype	Prenatal	Postnatal	Total
47,XXY	147 (90.2)	714 (89.7)	861 (89.8)
46,XY/47,XXY	15 (9.2)	48 (6.0)	63 (6.6)
48,XXXY	0	11 (1.4)	11 (1.1)
49,XXXXY	1 (0.6)	16 (2.0)	17 (1.8)
47,XXY/48,XXXY	0	2 (0.3)	2 (0.2)
48,XXY,+18	0	5 (0.6)	5 (0.5)
Total	163 (100.0)	796 (100.0)	959 (100.0)

Bojesen et al. (32).

Nonmosaic 47,XXY most often occurs because of nondisjunction of the sex chromosomes during the first or second meiotic division of gametogenesis in either parent. There is evidence that failure of the paternal XY or maternal XX chromosomes to pair and recombine in the usual way is a causative factor, as is also the case for autosomal trisomies (153,154). Paternal meiosis I errors account for approximately 50% of 47,XXY karyotypes (154). Of the remaining maternally derived karyotypes, 22–48% are due to meiosis I errors, 9–29% to meiosis II errors, 7% to unknown meiotic errors, and 3–16% to postzygotic mitotic nondisjunction (153–155). In prenatally ascertained cases, 54% are paternally derived and 46% are maternally derived (155). The maternal meiosis I errors contribute to a small overall association with advanced maternal age (156). Consistent with the situation for autosomal trisomies, advanced paternal age does not play a role. The phenotype does not appear to be influenced by the parental origin of the extra X chromosome, though few studies have specifically addressed this issue (157). The molecular basis of KS remains poorly understood. The phenotype is assumed to be caused by the expression of X-linked genes in one or more of the four pseudoautosomal regions of the X chromosome that escape inactivation. Preliminary data suggest that there are many more genes in this category on Xp than on Xq (153), but the identity and function of the critical genes have not been determined. Presence of an extra copy of the SHOX gene is probably the basis for the increased height in KS (158).

Although there is no consensus regarding a clinical definition of KS, a KS diagnosis should always be based on clinical findings combined with a confirmatory cytogenetic evaluation. On the other hand, a phenotypically normal man with very low-grade mosaicism should probably not have the diagnosis of KS.

Underdiagnosis and delayed diagnosis of KS is a major problem (32). Importantly, early diagnosis permits identification of speech problems and scholastic difficulties that require special measures to improve. Moreover, early diagnosis facilitates prevention or remediation of the long-term consequences of gonadal insufficiency.

From the earliest study, the syndrome was described as “not uncommon” (159) but the prevalence was unknown

until several large-scale sex-chromosome surveys were performed on newborns (22,27,160). Summarizing data from these studies across countries and ethnicities yields a prevalence estimate of 152 per 100,000 (32). Newer studies confirm that the true prevalence is in fact around 150 per 100,000 males or one in every 660 males (32), but with a major discrepancy between the prenatal and postnatal prevalence, indicating a severe lack of diagnostic activity, with only 25% of the expected number of KS being diagnosed postnatally and <10% of these being diagnosed before puberty. British data similarly find that only 26% of the expected number of adults with KS were diagnosed and only 4% of 10-year-olds (161). PCR-based screening methods to detect sex-chromosome aneuploidy are available but have not yet been validated on recent newborn population samples. If molecular screening for KS is offered, cytogenomic confirmation will be needed as well as infrastructure for follow-up and treatment of the patients with sex-chromosome abnormalities, and support services to help parents and caregivers deal with the uncertainties inherent in this type of diagnosis. Prenatal diagnosis of a fetus with 47,XXY karyotype should lead to professional genetic counseling, in order to inform the pregnant couple about the relatively good prognosis, but at the moment, 75% of couples expecting a child with KS choose termination (32). Owing to the fact that only approximately 25% of the expected number of men with KS is diagnosed, ascertainment bias is a major problem when interpreting data from different studies on different populations of KS patients. The phenotype of a KS patient diagnosed in childhood or at puberty may be different from what is seen in an adult KS patient. Most published data so far are hampered by such ascertainment bias. The most unbiased data available are the data from the prospective studies on boys diagnosed at birth, but the numbers of patients in these studies are small and hence the variability of estimates of certain clinical findings will be considerable.

As a consequence, one has to interpret prevalence data on clinical findings with great caution, and not readily extrapolate prevalence rates found in one population of KS patients to all KS patients.

#### 44.4.2 Congenital Malformations

There are no specific stigmata at birth, but an increased incidence of congenital malformations has been found (162). Minor congenital abnormalities were found in 26% with clinodactyly of the fifth finger as the most frequent (163) and major congenital abnormalities were found in 18% of KS boys, with cleft palate, inguinal hernia and cryptorchidism being the most frequent (163). Further evidence of highly increased prevalence of cryptorchidism comes from a large cross-sectional study from an andrological clinic, where 27% of KS patients had a history of maldescent of testes compared to 8% of the total number of patients attending the same clinic (162).

### 44.4.3 Testicular Development

The typical testicular histology includes hyalinization of seminiferous tubules, loss of germ cells and Leydig cell hyperplasia. In some KS patients, focal spermiogenesis may be found with the possibility of surgically extraction of sperm for in vitro fertilization (IVF) (164). The cause of the hyalinization of the testes with subsequent hypogonadism and infertility is unknown. There is a loss of spermatogonia from infancy (165) while hyalinization of the seminiferous tubules does probably not occur until midpuberty (166). At the beginning of puberty (167), testes grow to approximately 4 ml and thereafter shrink to the pathological adult size of <4 ml (168,169). Testes may be malfunctioning already during intrauterine life since micropenis seen in some newborn males with KS may be a result of decreased testosterone production in utero (170). Some find the normal surge in testosterone seen in the first 1–6 months of life attenuated in KS boys (170,171), while others find it similar to controls (172). Longitudinal studies on boys with KS before and during puberty have shown that even before puberty, testes are smaller than in normal boys (173). The levels of FSH, LH and testosterone are normal during the prepubertal period, but after the onset of puberty, a rise in FSH and LH and a decline in testosterone occur, compared to normal boys (168). In adult KS patients, not only decreased levels of testosterone but also decreased levels of insulin-like factor 3, a marker of Leydig cell function, are present (174). There is normal function of Sertoli cells in infancy since normal values of both inhibin B and AMH has been reported (171). At the end of puberty, inhibin B level diminishes, reflecting a loss of Sertoli cells (167). The hypogonadism, being regarded as a hallmark of KS, is relative rather than absolute as most of the KS patients have testosterone levels just below the normal range (162,175). Even though the levels of testosterone for many patients are within the normal range, levels of gonadotropins are usually elevated (152,162,175), indicating a relative hypogonadism that is reflected by the increased pituitary drive, and hence may be one of the causes of Leydig cell hyperplasia. The level of 17 $\beta$ -estradiol is relatively elevated compared to the low level of testosterone, being reflected by an elevated ratio between 17 $\beta$ -estradiol and testosterone (175).

### 44.4.4 Fertility

KS patients are usually considered infertile, but with the development of the testicular sperm extraction (TESE) and intracytoplasmic sperm injection (ICSI) methodologies, it is now possible to extract viable sperm from the testes by surgical biopsy and inject it directly into an extracted ovum. Worldwide more than 60 children have been born after successful ICSI treatment in KS couples (164,176). There have been concerns about an increased risk of chromosome aberrations in the offspring because an increased

number of both autosomal and sex-chromosome aneuploidy has been found in spermatozoas extracted or ejaculated from KS men (177). As a consequence, professional genetic counseling and options of prenatal diagnosis or even preimplantation genetic diagnosis should always be offered to couples seeking infertility treatment where the male is suffering from KS.

### 44.4.5 Hypogonadism

The frequent hypogonadism present may delay or reduce the development of normal male secondary sexual characteristics with less growth of beard, muscle bulk, and secondary body hair (152). The sexual function in KS patients has not been investigated in detail, but decreased libido has been reported in 70% after the age of 25 years (162). Hypogonadism may also be involved in the neurocognitive phenotype seen in KS. The long-term consequences of hypogonadism in KS are difficult to separate from the gene-dose effects of having an extra X-chromosome, because studies on comparable hypogonadal diseases (e.g. hypogonadotropic hypogonadism) are lacking because of their infrequency.

**44.4.5.1 Gynecomastia.** Gynecomastia is relatively frequent in puberty in normal boys and may be very troublesome. In KS, the prevalence is markedly increased, up to 50% (152) in some series, although the true prevalence probably is much lower (178). The decreased testosterone level in concert with an elevation in estradiol may cause gynecomastia (168). Testosterone treatment may lead to a regression of gynecomastia, but some KS patients choose to have the breast tissue removed surgically.

**44.4.5.2 Diabetes and the Metabolic Syndrome.** Epidemiological studies on both morbidity (45) and mortality (179) show an increased risk of diabetes, and clinical studies describe a strikingly high incidence of the metabolic syndrome and insulin resistance in KS (175,180), with increased cholesterol. KS subjects accumulate excessive amounts of body fat and especially truncal fat, and typically have a low level of physical fitness. Prospective studies in other populations have shown that low levels of testosterone (and sex hormone-binding globulin) can predict abdominal adiposity (181), the metabolic syndrome (182) and type 2 diabetes (183). Apart from the association between low testosterone, body composition, the metabolic syndrome and insulin sensitivity, low testosterone has been associated with an adverse CV risk profile, with increased C-reactive protein and triglycerides and decreased HDL-cholesterol (184). Although speculative, it seems possible that, on one hand, the hypogonadism contributes to the development of metabolic syndrome (and increase cardiac risk factors) but, on the other hand, protects against ischemic heart disease by increasing the amount of adiponectin (185). Corroborating this theory are data from a study on castrated men, showing a decreased risk of dying from acute myocardial infarction, in spite of a generally

increased mortality risk (186). It seems plausible that a vicious circle may exist where hypogonadism leads to abdominal obesity that leads to insulin resistance that may further aggravate the hypogonadism (187).

**44.4.5.3 CV Disease.** Mortality from CV diseases is increased in KS (43,179), even though the mortality from ischemic heart disease is reduced (43). One reason for the increased mortality may be mitral valve prolapse, which is described in a large proportion in one study (188), a condition that is related to increased risk of sudden death. The risk of hypostatic leg ulcers may be significantly increased (189) and may cause more serious morbidity and mortality from pulmonary embolism (43). Dysfunction of the fibrinolytic system has been proposed as a reason for this and increased activity of plasminogen activator inhibitor 1 in KS patients was described in one study (190), but further studies are needed to elucidate this.

**44.4.5.4 Osteoporosis.** Hypogonadism is a known cause of secondary osteoporosis in both females and males (191). A majority of studies shows a significant reduction in BMD compared to normal men although frank osteoporosis is less frequent (192–195). Epidemiological studies on morbidity and mortality did show an increased risk of being admitted to hospital with an osteoporotic fracture (forearm, hip and spinal fractures) (45) and an increased risk of dying from hip fractures (43), indicating that the reported reduction in BMD may mirror an important clinical problem. In a mouse model of KS (41,XXY), testosterone deficiency did not explain the reduced BMD, raising the possibility that the chromosome abnormality *per se* leads to reduced BMD (196).

**44.4.5.5 Cancer.** It has been debated whether gynecomastia may lead to increased risk of breast cancer. A register-based study on cancer in KS did not show an increased risk of breast cancer in KS (197), but a Swedish study (198) using karyotyping on nonmetastatic lymph nodes from men with breast cancer showed 47,XXY karyotype in 7.5% of the examined patients, equivalent to a 50-fold increase in risk of breast cancer. A study on mortality and incidence of cancer in a large cohort of KS subjects ( $n=3518$ ) showed that the risk of breast cancer was significantly elevated (199). In addition, a significantly increased risk of mediastinal germ cell tumors (197), an increased mortality risk from lung cancer, and non-Hodgkin lymphoma, and a significantly decreased risk of dying from prostate cancer are present.

**44.4.5.6 Cognitive Disturbances.** KS was found at increased prevalence among inmates of penalty institutions and institutions for the mentally retarded in studies in the early 1960s (200–202). This leads to the conclusion that KS was associated with criminal behavior and low intelligence, stigmata that were challenged by prospective studies of newborns screened for sex-chromosome disorders during the 1970s. In these later studies with long-term follow-up (150,151,203), the global intelligence was found to be near normal, but with decreased verbal

intelligence, delayed development of speech and high proportion of educational problems (204–207). A study on prenatally diagnosed KS patients showed a remarkably good outcome regarding intellectual performance (208), but this may reflect a higher socioeconomic status and better motivation in parents choosing to continue the pregnancy in spite of the KS diagnosis. One study on adults with sex-chromosome abnormalities detected at birth showed that the decreased verbal IQ and reading impairment persisted in adulthood (209), and also that a large variation in educational and vocational achievement was present. The reason for the delay in speech and decreased verbal intelligence is unclear, but an MRI study of the whole brain found diminished left temporal gray matter volume in five untreated KS patients, compared to five testosterone-treated KS patients and to normal controls (210). Another study on brain perfusion in KS patients, using single photon emission computed tomography, described a diminished lateralization of perfusion to the left, compared to normal controls and a negative correlation between lower perfusion in regions involved in language processing and scores in verbal tests (211). This may, in part, explain the decreased verbal performance seen in KS. Although the results are based on small sample sizes, they point toward a possible positive effect of testosterone on verbal performance in KS. This is in accordance with a study on verbal intelligence, pubertal development and testosterone levels, showing a positive association between testosterone levels and verbal IQ (212). Interestingly, a recent study showed impaired learning and memory function as well as testicular failure in XXY mouse model (41,XXY) (213,214) although there were no impairments in sociability (215). In another recent mouse model (41,XXY\*), there were no differences between wild type and the 41,XXY\* in locomotion, exploration and anxiety-related behavior, but memory recognition was clearly impaired (216).

Sexuality may be affected—fewer 47,XXY men are married, experience greater sexual dissatisfaction in general, and acknowledge unconventional sexual experiences compared to a control group and demonstrate a less-masculine-gender role (217).

**44.4.5.7 Psychiatric Diseases.** Increased incidence of psychiatric illness was reported in KS primarily based on screening for sex-chromosome abnormalities in penalty institutions, psychiatric hospitals and institutions for the mentally retarded (202). In a long-term follow-up study, an increased frequency of referral to psychiatric treatment was seen (151) and a survey for sex-chromosome aberrations among patients with schizophrenia found a four- to fivefold excess of KS (218). An epidemiological study on hospital admissions in KS showed a significantly increased risk of discharge with a psychiatric diagnosis (45), and patients may show an increase in schizophrenia-spectrum pathology (219). Overexpression of X-linked genes escaping X inactivation is thought to be involved in some of the psychiatric disturbances seen in KS (220).

**44.4.5.8 Criminality.** One follow-up study found no increased frequency of criminal behavior in KS judged by self-reported penalties (221). Another study following 34 KS patients for 10 and 20 years showed increased criminal behavior at 10 years of follow-up, compared with both hypogonadal men (from other causes than KS) and a control group (203) but after 20 years of follow-up, there was no significant difference in criminality (222). Recently published data on 32 KS patients diagnosed prepubertally or during puberty showed a large proportion of patients with severe psychosocial problems, with 69% having problems with controlling aggression, 28% offending the law and 18% having convictions (223).

**44.4.5.9 Treatment.** Treatment and care of patients with KS is a multidisciplinary task that ideally should involve speech therapists, psychologists, general practitioners, pediatricians, endocrinologists, urologists and infertility specialists. Infants with KS are rarely diagnosed because they lack KS-specific stigmata. However, some KS boys have micropenis, which in some have been treated successfully with topic testosterone cream or single injections with intramuscular testosterone. The most serious problem in early childhood is the delay of speech development affecting perhaps half of the boys with KS (151). Careful observation is needed in order to refer these boys to speech therapists if delay of speech is observed. The same holds true for learning disabilities, which were observed in 77% of boys with KS followed from birth to adulthood (151).

At puberty, when gonadotropins are rising, testosterone treatment should be initiated in order to secure a proper masculine development of sexual characteristics and also to secure a sufficient increase in muscle bulk and BMD (224). Testosterone treatment in pubertal KS boys has also been reported to increase energy, endurance, better mood and concentration and relations to others (225). Data on a group of KS diagnosed before and during puberty showed increased psychosocial problems in periods without testosterone treatment (223).

Treatment is recommended to be continued life-long in order to prevent osteoporosis, obesity, metabolic syndrome, and diabetes and to ensure optimal cognitive development. Although most clinicians taking care of KS patients believe that testosterone treatment has a positive impact, both physically and psychologically, there is no evidence-based confirmation of such an effect. Treatment in young hypogonadal men has been shown to have a positive impact on fat mass, muscle mass, and muscle strength, as well as sexual activity and related areas, and it improves positive aspects of mood (226). In older hypogonadal males, data suggest positive effects of treatment on visiospatial cognition and verbal memory (227).

Even though some KS patients have normal testosterone values, virtually all have increased gonadotropin levels, and all KS patients should receive testosterone treatment if their gonadotropins are elevated, even though their testosterone levels may be within the lower end of

the normal range. Certainly, patients should be treated if they are suffering from hypogonadal symptoms (lack of energy, decreased libido, and also including abdominal adiposity).

The aim of treatment should include normalization in LH and testosterone levels in the midnormal range, rather than low-normal nadir values of testosterone. LH can be normalized in virtually all KS patients if the testosterone dose is carefully titrated. It follows that many KS patients are not sufficiently treated because LH is often high. One should also focus on the subjective symptoms reported by the patient, especially to avoid high levels of testosterone, which can occur with injection therapy and may cause discomfort.

A possible negative effect of exogenous testosterone on fertility (or outcome of TESE and ICSI) has been debated, as well as treatment with aromatase inhibitors and HCG to increase intratesticular testosterone in order to increase the chance of sperm recovery by TESE (176). These interesting data are based on less recovery of sperm in five KS patients on long-term testosterone treatment and should be confirmed, preferentially in a randomized setting, before withholding testosterone treatment to young men with KS.

An outpatient management program for patients with KS is suggested in Box 44-3. Initially, testosterone

#### BOX 44-3 Proposed Assessment and Follow-Up Program for Patients with Klinefelter Syndrome

##### At baseline

Confirmation of karyotype, if necessary  
Sex hormones: testosterone, estrogen, SHBG, FSH and LH  
Fasting glucose and lipids  
Thyroid status, hemoglobin, hematocrit, Prostate specific antigen (PSA)  
Physical examination including BP, height, weight, waist, testes, breasts and varicose veins  
Bone desitometry (DEXA scan) and vitamin D status, p- calcium  
Information about the syndrome  
Initiation of androgen treatment (injections, transdermally or oral)  
Questions about well-being, physical activity, energy, sexual activity, libido  
Echocardiography  
Fertility issues

##### Annual (every three months initially)

Physical examination including BP, height, weight, waist, testes, breasts and varices  
Sex hormones: testosterone, estrogen, SHBG, FSH and LH (nadir values)  
Fasting glucose and lipids  
Thyroid status, hemoglobin  
Questions about well-being, physical activity, energy, sexual activity, libido

##### Every 2–5–10 years

Bone densitometry (DXA scan) and vitamin D status, plasma calcium, PSA

treatment should be followed with visits every 3 months until testosterone dose is adjusted, thereafter annually.

**44.4.5.10 Perspectives.** Not a single randomized, placebo-controlled study addressing the effects of testosterone in KS patients has been published. Of course, there is a major ethical problem in comparing, what we think of as a potent medication with placebo, especially in puberty where lack of treatment may lead to long-term negative consequences for the patients. But at least randomized, placebo-controlled studies on adults with KS could and should be performed, with testosterone preparations that will restore testosterone to normal values, in a population large enough to detect small changes in e.g. BMD, body composition, insulin sensitivity and also modalities of quality of life. Future studies will hopefully provide the evidence that is essential for optimizing the treatment of KS patients.

**44.4.5.11 Conclusions.** KS is a frequent cause of hypogonadism and infertility. It is the most common sex-chromosome disorder in man, with 47,XXY being the most common karyotype. The syndrome affects one in every 660 males but is severely underdiagnosed; only 25% of the expected number is diagnosed and only a minority of them before puberty.

In children, the main clinical findings are delayed speech development and learning disabilities as well as increased height and chryptorchism. In adults, the main reasons for diagnosing KS are infertility and hypogonadism.

KS is associated with a significant increase in risk of death and morbidity from a number of diseases. Testosterone treatment is recommended to all KS patients with elevated gonadotropins, in order to counteract the many harmful effects of hypogonadism on body composition, glucose and lipid metabolism, well-being, sexual function and other functions, both mentally and physically.

## 44.5 47,XXX SYNDROME

The 47,XXX karyotype occurs in approximately 84 per 100,000 female newborns when pooling data from large cytogenetic surveys (21,25–28,228–233) and was first described in 1959 by Jacobs et al. Unlike TS, this is essentially the same incidence found at amniocentesis (19), suggesting that prenatal loss after midgestation is rare. Prospective studies (209,234–239) have documented that females with 47,XXX have no distinguishing physical features, generally normal pubertal development and fertility, and intelligence that is within the normal range although as a group, full-scale IQ is lower than in control females (240). They are at risk for developmental delays, learning disabilities, and difficulties with psychosocial adjustment, while demonstrating significant individual variability (240). Importantly, only a minority of the expected number of females with 47,XXX are ever diagnosed (13%) (33). There is a substantial delay to diagnosis of a median of 18 years with wide variations. In other words, half of all diagnosed females with 47,XXX are

not diagnosed before adulthood. Mortality is increased in 47,XXX with a hazard ratio of 2.5 (95% confidence interval: 1.6–3.9), due to CV, urological and chromosomal diseases and congenital defects (33).

### 44.5.1 Genetic Background

In a study of 50 females with 47,XXX, 90% of the extra X chromosome was maternally derived (14). Molecular studies indicated that 64% of these were the result of meiosis I nondisjunction, 18% were the result of meiosis II nondisjunction, and 16% were the result of postzygotic nondisjunction. In another 31 conceptuses with 47,XXX karyotypes, 93.5% resulted from maternal nondisjunction with increasing maternal age being present in meiosis I errors but not in the meiosis II errors (241). There is no excess intrauterine mortality after amniocentesis (208).

### 44.5.2 Growth and Physical Development

Females with X chromosome trisomy cannot be identified by the presence of distinct physical differences at any age (240). The mean birth weights are somewhat lower than those of 46,XX girls. Many girls with 47,XXX will reach the 80th percentile for height during adolescence. The greater height seems to be attributable to increased growth of the lower segment relative to the trunk. Variability is great and stature is also influenced by parental heights in the usual multifactorial manner (158). Relative microcephaly is present in a minority, but average head circumference is significantly smaller than in controls (242). Those who have been followed prospectively from birth have a higher incidence of minor anomalies such as epicanthic folds, ear anomalies, and clinodactyly than females with an euploid karyotype.

### 44.5.3 Gonadal Function and Fertility

The vast majority of adult women with an extra X chromosome, probably go through puberty in the usual manner, is no different with regard to their sexual orientation, and lead a normal sexual life. Most also have normal reproductive capacities and bear children without sex-chromosome aneuploidy. Precocious puberty, early-onset menarche, and primary or secondary amenorrhea, including premature ovarian failure, have also been reported (240), and premature ovarian failure seems to be more prevalent than in controls (242). The incidence of sex-chromosome aneuploidy in the offspring of women with 47,XXX does not appear to be substantially increased, but has been reported.

### 44.5.4 Intelligence, Personality, and Behavior

Neuromotor deficits with an increased tendency for delays in the acquisition of gross motor skills are frequently

present and usually mild but may result in poor coordination and reduced athleticism. To somewhat greater extent than other individuals with sex chromosome abnormalities, females with 47,XXX karyotypes are often delayed in the acquisition of language and academic skills. IQ is usually 10–15 points below that of siblings, but mental retardation (IQ < 70) is rare (242). The average IQ in a prospectively followed group of 46 females was between 85 and 90 with a broad range (53–112) (238). Verbal IQ was significantly less than performance IQ, with deficits in both expressive and receptive language present in approximately 50%. A total of 70% had learning disabilities that required some form of educational intervention. A study of 11 adolescent girls with 47,XXX found, in addition to a reduced mean full-scale IQ, impaired scores on individual tests of attention, concept formation, mental flexibility, spatial thinking, verbal fluency, and basic academic skills compared with controls (234). Retention and retrieval of previously learned information did not differ from controls. These 11 adolescent girls with 47,XXX found the academic demands of high school particularly problematic. Nine of them required remedial placements but less than half completed their high-school degrees (243). From a social point of view, these girls were immature, passive, and prone to aberrant behavior and depression. Two of the 11, however, attended college and graduated. Employment tended to be unskilled but did range to include a self-owned small business (235).

A study examining the transition from adolescence to adulthood in these 11 young women with 47,XXX and nine female sibling controls found the former group to be less well-adapted, to experience more stress, to have more problems with work, leisure, and relationships, and to demonstrate more psychopathology (236). Psychological dysfunction was not wholly attributable to lowered intelligence though the latter did appear to exert an influence. Nevertheless, most of the group experienced mild disturbances and functioned reasonably well. The authors concluded that previously reported outcomes of antisocial behavior and severe psychopathology, including schizophrenia, are rare in women with 47,XXX and that the variability in behavioral phenotype is much larger than was originally appreciated. In a follow-up study of the same cohort, the 47,XXX group had the greatest impairment in IQ in comparison with patients with 45,X and 47,XXY (209). Behavioral characteristics are also present (149). There also seems to be an increased frequency of attention deficit/hyperactivity disorder, anxiety and mood disorders (209,234), and studies have found an increased risk of seizures and frequent EEG abnormalities (244,245).

#### 44.5.5 Renal System

Urogenital malformations, including cloacal exstrophy, Müllerian anomalies, renal anomalies, and lower

mesodermal defects (single umbilical artery, sacral vertebral fusions, and anal agenesis) have been reported in a small number of individuals (246), but an increased association with 47,XXX has not been substantiated by prospective studies. Routine investigation of the urogenital tract in females who are incidentally found to carry an extra X chromosome is probably unwarranted.

**44.5.5.1 Management.** Clinical problems should be dealt with in a similar manner as in other groups of patients. Many patients will probably benefit from speech therapy, occupational therapy and educational support during childhood and adolescence. The diagnosis of specific cognitive disorders is important and should preferably be made early in order to allow supportive measures in school (240,242). In cases of premature ovarian failure, HRT should be offered just as in TS (106).

### 44.6 X CHROMOSOME MOSAICISM

45,X/47,XXX, 45,X/46,XX/47,XXX and 46,XX/47,XXX mosaics are the product of nondisjunction in the mitotic division of a 46,XX zygote. The increased frequency with which these mosaic diagnoses are made prenatally indicates that many mosaic individuals are not identified postnatally.

The majority of these women have been described in the obstetrical literature, indicating that they do not, for the most part, have physical stigmata of TS, but some have and this often lead to early diagnosis. A study examining growth in approximately 50 women with triple X mosaicism found a direct correlation between height SD scores and the proportion of 46,XX cells in peripheral lymphocytes and an indirect correlation between these scores and the proportion of 45,X cells (247). The 47,XXX cell line did not seem to have a significant influence on stature. The interpretation of studies relying on one tissue in mosaic patients must be cautious, however, because the frequency of the cell lines in other tissues remains unknown. In vivo selection for the euploid cell line may occur over time.

Spontaneous pubertal development and menarche occur in many girls with these mosaic karyotypes. Premature ovarian failure or recurrent miscarriages have been observed in some women, but the majority have chromosomally and phenotypically normal pregnancy outcomes.

Adolescent women with this karyotype generally have neuropsychological profiles that are indistinguishable from controls, and developmental or learning problems are the exceptions rather than the rule (234–238,243).

### 44.7 SEX CHROMOSOME TETRASOMY AND PENTASOMY (POLYSOMY)

Although 45,X, 47,XXX, 47,XXY, and 47,YYY collectively occur with an incidence of approximately 1 in 400 newborns, sex-chromosome polysomies are much

less-frequent events. Unfortunately, their rarity precludes prospective studies that would present an unbiased picture. These individuals all have been identified clinically. The additional sex chromosomes seem to produce a lowering of IQ and an increase in somatic malformations. Similar to the trisomic sex-chromosome abnormalities (47,XXX, 47,XXY, 47,XYY) where adult height is increased in comparison with the background population, height is higher than normal in persons with four sex chromosomes, but seems to be progressively lower, the more sex chromosomes, and thus SHOX genes, are present (158). Whether this effect on height is explained by the increased expression of other genes on the sex chromosomes remains to be determined.

#### 44.7.1 Male—48,XXXY, 49,XXXXY, 48,YYYY, 48,XYYY and 49,XYYYY

The most significant effects of additional X chromosomes on phenotype are a reduction in intellectual functioning and an increase in malformations. Approximately 1 in 85,000 males is born with a 49,XXXXY karyotype (248), whereas 48,XXXY is somewhat more common with a phenotype that is intermediate between 47,XXY and 49,XXXXY. The latter diagnosis is usually made postnatally because of variable growth deficiency, facial coarseness and dysmorphism, hypogenitalism, and malformations of the heart and skeleton such as radioulnar synostosis or congenital hip dislocation. These men have significant cognitive and behavioral problems with a variable IQ between 20 and 60. There are no consistent prenatal findings, but prenatal diagnosis has been described in fetuses with cystic hygroma, abnormal posturing of the lower extremities, and small genitalia (248). Testicular histology resembles the situation in KS and most will experience hypergonadotropic hypogonadism and should probably receive testosterone supplementation in the same manner as patients with KS (249).

Males with poly-Y karyotypes containing three Y chromosomes (48,XYYY) are usually identified by tall stature and aberrant behavior (impulsivity and low frustration tolerance), with low-normal or subnormal intelligence, developmental delay, abnormal dentition, radioulnar synostosis, and hypergonadotropic hypogonadism (250). Normal-appearing external genitalia seem to be the rule, but testicular biopsies have demonstrated variable abnormalities, and azoospermia is common. Recurrent respiratory infections, inguinal hernias, and additional abnormalities of the humerus, radius, and ulna have also been reported. Minor anomalies include brachydactyly, clinodactyly, and single transverse palmar creases. The phenotype is, however, inconsistent.

Males with four Y chromosomes are even fewer in number. In addition to the features outlined above, case reports suggest that these males are ascertained at birth because of the presence of craniofacial dysmorphism, including trigonocephaly, hypertelorism, upslanting palpebral fissures,

epicanthic folds, low-set ears, and micrognathia or prognathia. These boys are not uniformly tall and appear to have more severe intellectual deficits, hypotonia, motor delay, and speech delay than their counterparts with three Y chromosomes. Little is known about the extent of phenotypic variability (250).

#### 44.7.2 Female—48,XXXX and 49,XXXXX

More than 40 women with a 48,XXXX karyotype have been described. These individuals are often tall with an average height of 169cm (250). Otherwise there are no consistent clinical features. Epicanthic folds, hypertelorism, nystagmus, radioulnar synostosis, and clinodactyly are often reported. Genitalia are generally normal, but secondary sex characteristics may be incompletely developed. In one series, half of the adult women with this karyotype had normal menarche and menopause (250). With one exception, mental retardation has been consistently reported, with an average IQ of 60, but a range from 30 to 75. There is no characteristic behavioral phenotype.

The penta-X karyotype is less common than 48,XXXX, and there is a paucity of information on adult women with this karyotype, but primary ovarian failure has been noted in one case (251). All these individuals demonstrate a more markedly abnormal physical and developmental phenotype than is seen in girls with quadruple-X karyotypes. Unlike other sex-chromosome polysomies, girls with 49,XXXXX often demonstrate intrauterine and postnatal growth retardation, so they are more likely to be short than tall. The phenotype consists of microcephaly and coarse facial features, including hypertelorism, epicanthic folds, up-slanting palpebral fissures, a depressed and/or broad nasal bridge, and a short broad neck. Congenital heart defects, particularly ventricular septal defect and patent ductus arteriosus, radioulnar synostosis, generalized joint laxity with multiple dislocations, and talipes equinovarus have also been reported. Minor anomalies include single transverse palmar creases and clinodactyly. Puberty is delayed, secondary sex characteristics are incompletely developed, and several girls have been noted to have small uteri. Fertility remains unknown. Mental retardation has been universal with an average IQ of 50 and no distinct behavioral profile. The mechanism of origin seems to be successive maternal meiosis I and II nondisjunction in most instances (252–254).

### 44.8 47,XYY KARYOTYPE

47,XYY syndrome is present in approximately 1 in 1000 newborn boys, however, only a minority of about 15% are diagnosed postnatally, leaving the entire literature on 47,XYY heavily biased (34). The median age at diagnosis is 17.1 years, thus, half of all cases are diagnosed as adults. This sex-chromosome aneuploidy

is not characterized by distinct physical features and, because there does not appear to be a recognizable pattern of neurodevelopmental or behavioral characteristics, the use of the term *syndrome* may be inappropriate. Males with an extra Y chromosome are phenotypically normal and most never come to medical attention. This seems to be reflected in the paucity of recent clinical literature on individuals with this karyotype. There are relatively small numbers of controlled prospective studies, so knowledge of the medical and psychological profiles of boys with this chromosome constitution remains subjected to both ascertainment and reporting biases. However, Ratcliffe (151) reported the clinical features of 19 males ascertained at birth by consecutive newborn cytogenetic screening and followed to the ages of 16–27.

Mortality is clearly increased in 47,XYY syndrome with a hazard ratio of 3.6 (95% CI 2.6–5.1) corresponding to an average loss in lifespan of 12.4 years (34). The increased mortality is due to a range of causes such as cancer, pulmonary, neurological and urological diseases (34).

### 44.8.1 Etiology

The additional Y chromosome is derived from paternal meiosis II nondisjunction or postzygotic mitotic nondisjunction (255). 47,XYY syndrome is therefore not associated with increased maternal or paternal age. Not surprisingly, the incidence of 47,XYY syndrome at amniocentesis is similar to that at birth, indicating that few of these fetuses are lost in the second and third trimesters of pregnancy.

### 44.8.2 Growth and Physical Development

The length and weight of newborns with an extra Y chromosome are indistinguishable from others and there are few, if any, clinical differences to suggest the karyotype (256,257). There have been reports that the presence of the extra Y chromosome is more often associated with renal malformations and Potter sequence (258). There are also reports describing CNS anomalies in fetuses with this karyotype, including one with isolated agenesis of the corpus callosum and another with Dandy Walker malformation (259). Coincidental association is possible though it is intriguing that a fetus with 49,XYYYYY was found to have hypoplasia of the corpus callosum and cerebellum and a large posterior fossa cyst causing secondary hydrocephalus (260). No increase in any major anomaly has been seen in prospective studies of this karyotype with unbiased ascertainment at birth. There are rare reports of radioulnar synostosis in boys with 47,XYY (261) though this finding is more consistently associated with the presence of more than two Y chromosomes (48,XYYY and 49,XYYYYY) or with mosaic karyotypes that include multiple Y chromosomes.

Although an increased frequency of minor anomalies such as clinodactyly, inguinal hernia, and pectus carinatum has also been suggested, no consistent clinical picture has emerged. Similarly, no distinction in growth or appearance can be made between infants with 47,XYY and those with 46,XY karyotypes. For this reason, the karyotype is often found coincidentally.

Accelerated linear growth is present as early as age 2 and boys with 47,XYY are an average of 7.6 cm taller than their peers by the onset of puberty (151). The onset of puberty is on average 6 months later than in controls and the pubertal growth spurt is of longer duration, producing an average final height of 188 cm (151). Gron et al. documented larger craniofacial dimensions in these males than were present in controls (262), and Geerts et al. found increased height, weight, and head circumference in this population (257), and the increased height is thought to be due to the expression of additional genes involved in linear growth (158).

### 44.8.3 Gonadal Function and Fertility

Pubertal development, testicular histology, and spermatogenesis are most often normal. In a number of instances, smaller-than-normal testes, decreased spermatogenesis, spermatogenic arrest, subfertility, and sterility have been reported. Persistence of the extra Y chromosome in germ cells can impair testicular tubular development and result in low sperm counts. However, it appears that XY pairing and recombination usually occur normally in 47,XYY, the extra Y chromosome being lost during spermatogenesis (263,264), so that many XYY men have fathered chromosomally normal children. It has generally been observed that reproductive risks for males with 47,XYY are no higher than for euploid males, despite the fact that in situ hybridization studies demonstrate a lower frequency of single Y-bearing sperm than expected and a variably higher rate of disomic XX, XY, and YY spermatozoa in males with 47,XYY (263–265). However, results vary substantially between individuals (264). These observations, based on the collective analysis of several hundred sperm in 47,XYY and control men, reach a very high degree of statistical significance. However, the absolute frequencies of XX-, XY-, and YY-bearing sperm from 47,XYY men remain low at <1% (264). It appears that the increased rate of sperm aneuploidy is no greater than in males with oligoasthenoteratozoospermia and a normal karyotype (146). With occasional exceptions (266), the sperm of men with 47,XYY do not appear to have a higher rate of autosomal disomy than those of controls. In half of the case reports describing autosomal aneuploidy in offspring born to men with 47,XYY, the aneuploidy has been of maternal origin (267). There is no indication that the sexual orientation of boys and men with 47,XYY is any different than it is in those with a 46,XY karyotype.

#### 44.8.4 Intelligence, Personality, and Behavior

The commonest indications for karyotyping in boys with 47,XYY are developmental delay and/or behavioral difficulties. Population-based studies have demonstrated that intellectual abilities tend to be slightly lower on average than those of siblings and matched controls and boys with an extra Y chromosome are more likely to require educational help. However, intelligence is usually well within the normal range. Ratcliffe (151) reported average verbal and performance IQs of 99 and 104 among 19 boys and men identified at birth and followed prospectively, compared with 114 and 115 in controls. Interestingly, boys with KS, as well as females with 47,XXX, have significantly smaller whole-brain volumes on MRI than age- and sex-matched controls, whereas this difference is not seen in males with 47,XYY (268). During school age, learning disabilities requiring educational intervention are present in approximately 50% and are as responsive to therapy as they are in children with normal chromosomes (151,221). Expressive and receptive language delays and reading disorders are common. Hyperactivity, distractibility, and temper tantrums have been present in some boys and may affect their school performance (269). Aggression is not frequently observed.

Older psychological studies suggested that certain personality traits, such as infantilism, lack of emotional control, increased impulsiveness after emotional stimulation, and a weak concept of self were so characteristic that men with 47,XYY could be recognized by psychological tests alone (270). Such findings are largely contradicted by prospective studies, in which males with 47,XYY are behaviorally indistinguishable from controls.

There may be a weak predisposition to behavioral problems in the setting of a stressful environment as adolescents and young adults with 47,XYY from dysfunctional families seem to be less well adjusted than their siblings. This is not true in those whose environments have been more supportive. An important bias is that any psychosocial difficulties experienced by an individual with 47,XYY are likely to be attributed to his karyotype when they could well be caused or influenced by a myriad of environmental factors.

There are case reports describing pervasive developmental delay in a few boys with 47,XYY but these may be the result of ascertainment bias. Because the vast majority of boys with an extra Y chromosome do not have pervasive developmental delay, Nicolson et al. (271) speculate that the extra Y chromosome might set the stage for aberrant brain development. Pervasive developmental delay could then develop in a small number of these boys when a sufficient number of additional predisposing factors, such as a family history of learning or social difficulties, are present.

The karyotype 47,XYY has probably aroused more public interest than any other chromosome abnormality,

because the extra Y chromosome was demonstrated in tall, mentally retarded criminals. Prospective studies of XYY males detected at birth are now starting to yield data on adults. Gotz et al. (221) identified 16 newborns with 47,XYY and 13 newborns with 47,XXY by population screening over a 12-year period ending in 1979. Twenty years later, these men were compared with 45 controls with normal karyotypes and normal intelligence for rates of antisocial behavior and criminal convictions. The males with 47,XYY demonstrated a significantly higher frequency of criminal convictions and antisocial behavior in adolescence and adulthood than did controls, but multiple regression analysis suggested that these differences were associated with lowered intelligence. The same observations were not seen in the Klinefelter group, but the small number of subjects precluded any firm conclusions.

There is some suggestion, therefore, that the extra Y chromosome leads to a slightly increased risk of social maladjustment. There is little information on adaptation in an unselected group of 47,XYY adults. However, it would seem that the above-noted cognitive and psychological characteristics combined with environmental stressors might increase their risk for problems with the law.

#### 44.8.5 Health

Severe facial acne has occasionally been reported. There is poor evidence for a purported increase in varicose veins, electroencephalographic, or electrocardiographic abnormalities. Several reports of hematologic malignancies in boys and men with 47,XYY appear to be coincidental and due to the routine inclusion of a karyotype in the diagnostic workup (272,273). The increased mortality in 47,XYY syndrome warrants future studies investigating the specific background.

### 44.9 STRUCTURAL ABNORMALITIES OF THE Y CHROMOSOME

The human Y chromosome shows considerable inter-individual variation in structure, particularly length. This trait is stable and inherited, father and son generally having identical Y chromosomes. When a structural abnormality is diagnosed, especially in utero, comparison with the paternal Y chromosomes is essential for interpretation, and the possibility of nonpaternity must always be considered. Structural abnormalities of the Y chromosome are not usually well characterized by routine karyotyping, so molecular and in situ hybridization studies are generally recommended.

Clinical consequences of structurally abnormal Y chromosomes depend on the loci deleted, any associated mosaicism, and the tissue distribution of various cell lines. Derivative Y chromosomes are unstable and often associated with mosaicism. Broad categories include

those with loss of SRY on the Y chromosome short arm leading to a female phenotype in the TS spectrum, loss of azoospermia factors (AZF) on the long arm leading to phenotypically normal males with infertility, and mosaics typically with 45,X whose phenotypes range from males to mixed gonadal dysgenesis to females with TS.

### 44.9.1 Yp Deletions

Individuals who have neither molecular nor cytogenetic evidence of the testis-determining factor (SRY) on Yp11, just proximal to the pseudoautosomal region, are not usually masculinized. Persons with 46,X,del(Yp), therefore, have a Turner phenotype that often includes lymphedema, streak gonads, infertility, and a significant risk for gonadoblastoma. They may differ from TS by the absence of short stature (274).

### 44.9.2 Yq Deletions

Deletions of the long arm are thought to be the result of intrachromosomal recombination involving highly repetitive, palindromic DNA sequences unique to the Y chromosome. These deletions do not involve the SRY locus and do not affect testicular determination; hence, they produce phenotypic males. Some such patients have normal- or near-normal-sized testes with histologic evidence of defective spermatogenesis, whereas a few have had cryptorchidism or small testes. Each of the currently recognized common microdeletions of AZF regions contains several genes thought to be relevant to spermatogenesis, and each gene is often present in multiple copies. The complexity of Y chromosome sequences makes investigations challenging (275). Although some Yq deletions are visible on karyotype, molecular techniques are commonly required.

The palindromes characterized thus far include the proviral sequences HERV15yq1 and HERV15yq2; recombination between these results in a proximal deletion of Yq11 (276). The region lost in this deletion is identified as AZFa. Several candidate genes for spermatogenesis are found in this region including DEAD-box protein 3 and ubiquitin-specific protease 9 (USP9Y) (277). Point mutations and deletion of USP9Y have been discovered in a few males with milder deficits in spermatogenesis (277). Typically, deletions of AZFa result in severe azoospermia with Sertoli-cell-only syndrome, in which there is a complete absence of germ cells on testicular biopsy (278).

Initially thought to be nonoverlapping, the other commonly deleted regions were termed AZFb and AZFc in order from proximal to more distal Yq. Although overlapping deletions have now been identified, the terminology remains widespread. Within AZFb, deletions occur between palindromes P5 and proximal-P1, while recombinations between palindromes P5 and distal-P1 and P4 with distal-P1 result in deletions that overlap AZFb and

AZFc (277). The most common deletion involves loss of the AZFc region of Yq11 between palindromes b2 and b4 (279). Spermatogenesis candidate genes in AZFb include RBMY1A1, an RNA-binding motif protein, and in AZFc, deleted in azoospermia. Located proximal to AZFa is a putative growth control locus (GCY) as deletions involving this region are associated with short stature (280). The incidence of Yq deletion among azoospermic males varies widely, with figures as high as 55.5% in a group with narrowly defined idiopathic Sertoli-cell-only syndrome (281). Foresta et al. (282) reviewed more than 4800 published patients and found that the overall prevalence of these microdeletions ranged from 2.9% in unselected oligospermic men to 11% if other causes of oligospermia were ruled out (“idiopathic”), whereas in azoospermic men, the prevalence was higher, ranging from 7.3% in unselected patients to 18% in the “idiopathic” group.

Interestingly, a small number of families have been reported, in which Yq microdeletions of AZFc have been transmitted in natural conceptions to male offspring. Most cases involve a father having a single infertile son. Two men have been described who passed on large AZFc deletions to infertile sons; three in one case (283) and four in another (284). These families demonstrate that Y-chromosome microdeletions are subjected to variable expressivity and do not necessarily imply a life-long history of infertility.

A couple in which the male has a Yq microdeletion can be offered assisted reproduction. If sperms are retrievable, either from ejaculate in the case of oligospermia or by testicular biopsy, IVF with ICSI into a harvested egg can be performed. Fertilization and pregnancy rates do not appear to be affected by the presence or absence of Yq deletions (285). Male offspring in these situations would necessarily inherit their father's Y chromosome anomaly and attendant infertility. One son reportedly inherited a larger deletion than his father's (286). Concern has also been raised about a potential association with 45,X/46,XY mosaicism and Yq microdeletions, suggesting that transmission of Y chromosomes with microdeletions could give rise to mosaic offspring (287). Approximately 5% of oligospermic males participating in ICSI programs have nonmosaic Y-chromosome microdeletions (288). It has therefore been recommended that all males with reduced or absent sperm counts seeking assisted reproductive technologies be screened for Y-chromosome deletions.

### 44.9.3 Dicentric Yp

Dicentric Yp is among the most common Y-chromosome rearrangements and is often associated with the mosaic karyotype 45,X/46,X,dic(Yp). The dicentric Y chromosome may be created during male gametogenesis, the observed mosaicism presumably reflecting postzygotic instability. It may also result from a very early postconceptional mitotic event. Not surprisingly, the phenotype is highly variable and includes females with varying degrees

of masculinization and TS characteristics, to males with or without genital anomalies. One review found 27% of individuals with idic(Yp) had a male phenotype (274).

The determinants of phenotype within this wide spectrum are not clearly understood. Though the presence or absence of SRY and other Y chromosome genes for spermatogenesis and stature, the presence of a 45,X cell line, and the proportion and tissue distribution of these various cell lines would all reasonably be expected to contribute to phenotype, only limited genotype–phenotype correlations can be made (289,290). Cytogenetic studies to estimate the proportion of cells containing the dicentric Y chromosome may be misleading because of inherent dicentric instability. It appears that the majority of dicentrics contain two copies of most of the functional euchromatin with break points close to or within the heterochromatic region, with SRY usually present. Occasionally, males with this karyotype are fertile, presumably because of the presence of one or more Y-linked genes controlling spermatogenesis. More frequently, however, phenotypic males have significant deletions of Yq resulting in short stature and azoospermia.

The presence of Y material is known to predispose to gonadoblastoma, so gonadectomy is recommended for these individuals.

#### 44.9.4 Dicentric Yq

Dicentric Yq is less common than dicentric Yp, but they share many characteristics. It is generally associated with 45,X mosaicism, and the phenotypic spectrum is comparable. The recombinant chromosome loses a variable amount of Yp, so that some of these individuals are males and others are females. Once again, the presence of SRY in a proportion of cells does not guarantee a male phenotype (290). Isochromosome Yq is rare and, when present, usually results in females with little or no masculinization. Gonadoblastoma has been reported (291).

#### 44.9.5 Ring Y

Rings and very small Y-derived marker chromosomes can best be characterized with the use of molecular and in situ hybridization techniques. Many of the rings represent complex Y-chromosome rearrangements, some have multiple centromeres, and all are generally unstable. The phenotype varies widely depending to some degree on the extent of Y-chromosome rearrangement and deletion, but generally a 45,X cell line is also present and there is an overlap with the dicentric spectrum described above (292).

#### 44.9.6 Pericentric Inversions of the Y

Pericentric inversions of the Y are heritable and have no phenotypic effects. One form leading to an almost metacentric Y chromosome is common in India and probably

represents an ancient mutation. The paternal Y chromosome should be checked when the condition is diagnosed prenatally.

### 44.10 PRENATAL DIAGNOSIS OF SEX CHROMOSOME ABNORMALITIES

As more couples are availing themselves of CVS or amniocentesis for both fetal and maternal indications, sex-chromosome aneuploidy is an increasingly common prenatal finding. Most geneticists and obstetricians would agree that these counseling sessions are more complex and challenging than those for autosomal trisomies, in which the phenotypes are generally less subtle from a physical, developmental and prognostic point of view. The goal of counseling is to present the couple with accurate information that empowers them to make an informed decision about the pregnancy (see also Chapter 21).

The counselor can be faced with at least two different scenarios. When there has been a sonographic identification of major fetal anomalies such as hydrops, the couple will have received some information before the prenatal diagnostic procedure. In this scenario, they generally arrive for counseling with a highly variable degree of understanding that there are physical problems with the fetus that may be the result of a chromosome abnormality. On the contrary, when prenatal diagnosis has been performed because of advanced maternal age, the presence of “soft” markers for autosomal trisomies, or a positive prenatal screen, the finding of sex-chromosome aneuploidy is often incidental and completely unanticipated.

Irrespective of the particular situation, the general principles of prenatal counseling apply. The couple is often aware of “an abnormality” on arrival at the counselor’s door. For many couples, the term *chromosome abnormality* is synonymous with Down syndrome because this is the most common type of aneuploidy in live-born children and the only one with which they may have personal experience. They are usually in a state of extreme distress that is exacerbated by fear of what they are about to be told. A compassionate acknowledgment of this at the outset is often helpful and should be followed by a brief attempt to elicit what details the couple already knows. The counselor should then proceed as quickly as possible to a discussion of the particular chromosome finding and its implications, allowing the couple to dictate the agenda with their questions. Management options, which generally include continuing or ending the pregnancy, should be approached in a nonjudgmental and nondirective manner. As in any counseling situation, empathic verbal and body language are extremely important. The counselor must be prepared to respond compassionately to expressions of grief and to repeat the information as often as necessary.

Of the more common sex-chromosome aneuploidies (45,X, 47,XXX, 47,XXY, and 47,XYY), only TS and related mosaic karyotypes are often associated with

major congenital anomalies and an increased risk of pregnancy loss. TS counseling will depend to a great extent on the mode of ascertainment. If the indication for prenatal diagnosis is fetal hydrops on a midtrimester ultrasound examination, there is a high probability of intrauterine death. Because the majority of 45,X losses occur in the first trimester, this is not true of a fetus with 45,X and normal sonographic findings that are incidentally ascertained by second-trimester amniocentesis for advanced maternal age. The content and emphasis of the counseling session will be dramatically different in these two situations.

In general, however, counseling for common sex-chromosome aneuploidies should include a thorough discussion of the highly variable spectrum of physical findings, which may be cosmetically significant in 45,X and to a lesser extent 47,XXY, but is essentially restricted to taller than average stature in 47,XXX and 47,XYY, but with increased mortality rates in all four syndromes. The involvement of sex chromosomes suggests to many couples a fundamental difference in the gender of their child. The counselor should volunteer the fact that the extra or missing chromosome usually precludes fertility in KS and TS but has no known impact on sexual orientation and the capacity for normal sexual function. The mention of hypogonadism in TS and KS must be accompanied by a review of available treatments, including cosmetic surgery for gynecomastia and testicular enlargement in 47,XXY. HRT is a mainstay of treatment in both conditions, and GH therapy is an option in the former. Under some circumstances, a referral to a pediatric endocrinologist during the pregnancy is appropriate and helpful with regard to decision-making. The couple should also be made aware of the availability of alternative parenting options (IVF with donor egg or sperm, ICSI, adoption) for the adult individual with TS or KS.

Perhaps most importantly, the counselor must thoroughly review the intellectual, psychological, and behavioral observations summarized above and make absolutely clear the difference between distinct learning disabilities (which are often present and amenable to educational support) and mental retardation (which is almost always absent and implies a permanent degree of disability). For 47,XXX and 47,XYY, emphasis should be placed on the fact that most of these children would have gone through life undetected, particularly in a stable environment. The importance of a supportive home environment cannot be overemphasized as children with sex chromosome aneuploidy from stable and nurturing families have no more psychological disorders than do their siblings (237). Abramsky and Chapple (161) recognized that the label of a “chromosome abnormality” may lead to a worse perception of the phenotype (and an increased likelihood of pregnancy termination) than would otherwise be the case. How many couples, they wondered, would consider termination of a euploid pregnancy if they were told the child’s IQ would be normal but 10–15

points lower than that of his or her siblings? They also draw attention to the fact that background rates of learning disability, developmental delay, and psychological difficulties in chromosomally normal children should be quoted to enable the couple to put the implications for children with sex-chromosome aneuploidy in context. There is no such thing as a “perfect” child.

At least 15 studies published between 1982 and 2011 examined pregnancy termination rates after the prenatal diagnosis of sex-chromosome abnormalities in individual centers in North America, Europe, Scandinavia, Israel, and Australia (35,293). Termination rates were highly discrepant among studies and across regions, some of which excluded pregnancies ascertained because of ultrasound anomalies and many of which were complicated by a small number of patients and/or the involvement of a number of different counselors. Termination rates were highest for 45,X (54–100%), reflecting the fact that more pregnancies with monosomy X were ascertained because of ultrasound findings. The rates varied markedly for the other sex-chromosome aneuploidies. Between 17% and 92% of pregnancies diagnosed with 47,XXY were ended, while the equivalent figures were 17–67% for pregnancies with 47,XXX and 10–75% for pregnancies with 47,XYY. The average rate of termination for all sex-chromosome abnormalities was 50%.

A number of factors may influence the decision about whether to continue a pregnancy in the face of these karyotype results. At least two studies suggest that older parents with a higher number of previous pregnancies are more likely to continue their pregnancies (35,294), whereas another found couples with a higher number of previous children were less likely to continue their pregnancies (295). Others suggest that black, Hispanic, and Arab parents are more likely to continue their pregnancies than Caucasian and Jewish parents (296), but many have not found any racial predilection for one choice over the other. Not surprisingly, pregnancies with normal ultrasound findings and mosaic sex-chromosome abnormalities are continued more often than those without (297). Higher termination rates have been found when counseling is performed by an obstetrician as opposed to a medical geneticist, genetic counselor, or pediatrician (294,298,299). There is speculation that a greater awareness of medicolegal risk and less familiarity with the natural history of sex-chromosome aneuploidies influences the counseling of obstetricians. Many studies have demonstrated a significant decrease in the percentage of patients choosing termination of pregnancy over time (293,300), hopefully reflecting an increasing understanding and more accurately optimistic portrayal of sex-chromosome abnormalities resulting from long-term prospective studies.

In one of the few large reviews, of 169 pregnancies in which 45,X, 47,XXX, 47,XXY, and 47,XYY were diagnosed between 1971 and 1997, 32% of couples chose to continue their pregnancies (300).

Of those who had normal ultrasound examinations, 40% continued their pregnancies; the equivalent figure in pregnancies with abnormal ultrasound examinations was 18%. Half of the remaining pregnancies were ended on the basis of ultrasound findings alone as many of them consisted of 45,X-associated fetal hydrops or cystic hygroma, both of which predict a poor prognosis. Among pregnancies with a normal ultrasound examination, those with a diagnosis of 47,XXX and 47,XYY were continued significantly more often than those with a diagnosis of 45,X and 47,XXY. Fifty percent of sonographically normal pregnancies with mosaic findings were continued, compared with 35% of pregnancies with nonmosaic karyotypes. The method of prenatal diagnosis as well as the marital status, education, and profession of parents did not exert a significant influence on decision-making. There was a significant difference in parental decision-making over the course of the study, likely related to the lack of adult outcome data before 1990. None of the couples continued their pregnancies between 1976 and 1979, in contrast with a 46% continuation rate between 1995 and 1997. Recent studies have reported continuation rates as high as 60–70%. Interestingly, follow-up of a small number of these children suggests that they are developmentally ahead of children with sex-chromosome aneuploidies that were diagnosed by newborn screening. The fact that these parents made a conscious decision to continue their pregnancies, possibly combined with the advantage of early anticipatory intervention, appears to have had a positive effect on outcome.

## Biography

**Claus Højbjerg Gravholt**, Medical doctor, PhD, Dr med. sci. Specialist in adult endocrinology and internal medicine.

Gravholt is currently working as a consultant and senior researcher at Aarhus University Hospital, Denmark, Department of Endocrinology and Internal Medicine, and the Department of Molecular Medicine. He has worked clinically and scientifically with sex-chromosome abnormalities for the last 18 years. He has performed clinical, genetic, epidemiological and experimental studies. He has published more than 100 original publications and review papers. He is an active participant in the international Turner and Klinefelter syndromes research community, as well as national and international research societies.

His main research activities are in the endocrinology of Turner and Klinefelter syndromes, focusing on GH, IGFs, androgens and estrogens, and also aspects of diabetes and metabolism, epidemiology, cardiology, and genetics.

### 45.1 INTRODUCTION

Over the past two decades, the knowledge generated by the completion of the Human Genome Project (1990–2001) has refined and revolutionized our understanding of the role of genomic deletion, duplication and rearrangement in human disease. Utilization of new laboratory techniques such as chromosome microarray analysis (CMA) and application of these new tools to genomic analysis of patients with a wide variety of disorders has been highly informative. It is now the standard of care to utilize CMA testing as a first-tier test for many diagnostic categories, resulting in improved diagnostic accuracy, more precise delineation of deletion and duplication breakpoints, and the discovery of new genomic syndromes (1). In addition, the fruits of the Human Genome Project have produced extensive genomic databases, and it is now possible to correlate the genomic coordinates of deletions or duplications with the genome sequence and identify the genes whose dosage is altered. Our knowledge about deletions and other structural abnormalities of the autosomes has therefore changed dramatically over the past 5 years. This is manifest in more precise delineation of “classic” microdeletion syndromes, description of new microdeletion syndromes, and increased knowledge of the underlying genomic architecture that predisposes to the recurrent rearrangements.

The human genome is composed of  $3 \times 10^9$  base pairs of DNA, which are estimated to code for about 22,000–23,000 structural genes (2). Approximately 10–15% of the DNA codes for genes (transcripts and their regulatory sequences), while the remainder consists of repeated

sequences and sequences of unknown function. When examined at metaphase at the 550-band stage (standard cytogenetic analysis), an “average” chromosomal band contains approximately  $5 \times 10^6$  DNA base pairs that could code for as many as 100–200 genes. Therefore, patients with cytogenetically visible chromosomal abnormalities involving gains or losses of a single band or part of a band have abnormal dosage for numerous genes. Given this, it is not surprising that almost all individuals with a cytogenetically detectable chromosomal imbalance demonstrate some phenotypic abnormality. However, CMA analysis can identify deletions and duplications that are more than an order of magnitude smaller than karyotyping, and recent work demonstrates that phenotypically normal individuals also have deletions and duplications of genomic material, including regions that contain genes (3). In fact, the total number of genes in a healthy individual can vary by more than 100 genes, indicating that loss of one allele of some genes is not deleterious. These deletions and duplications found in healthy individuals have been termed copy number variants (CNVs), and a large part of the work involved in interpreting the results of a CMA analysis is focused on determining which CNVs are pathogenic and which are benign. In general, pathogenic alterations are copy number changes that are not seen in the normal population and contain genes that cause disease when deleted or duplicated; however, this is currently an incomplete science, as only a subset of dosage-sensitive genes are known, and analysis of copy number variation in controls has not been done systematically.

The curated data on controls is available through public databases that collect information from a wide variety of studies using different array platforms, different bioinformatics algorithms and different analytical standards (e.g. Database of Genomic Variants; <http://projects.tcag.ca/variation/>). Nevertheless, many new syndromes caused by deletions and duplications have been identified, and work on both patients and controls is ongoing.

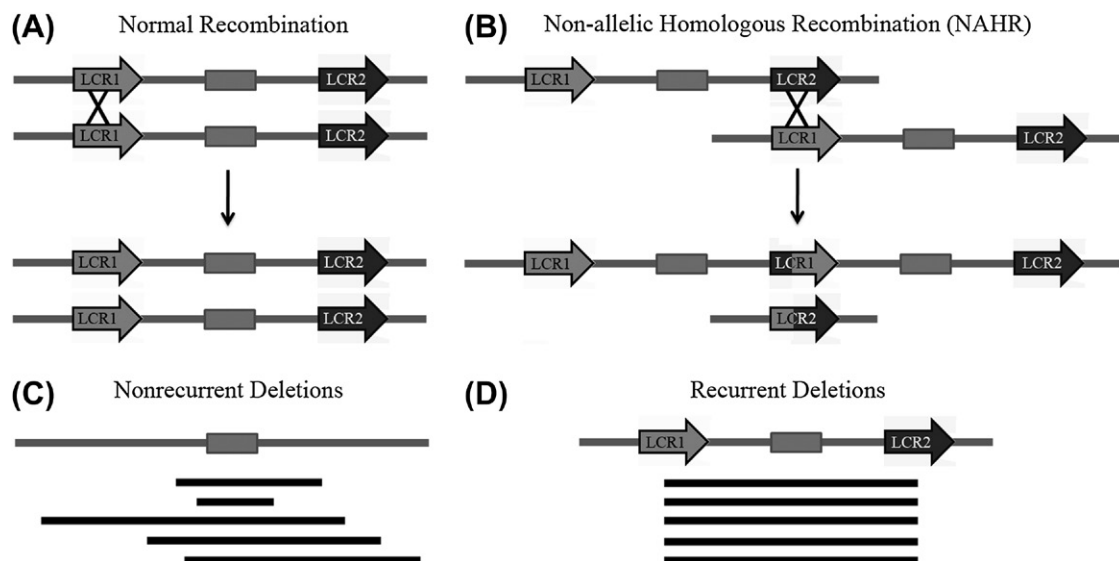

The diagnostic yield of CMA testing reported in the literature ranges from 5–20% of patients tested, depending on the clinical indications for testing and the characteristics of the microarray used (1,4–6). Deletions are the most common type of genomic alteration associated with human constitutional disease. Clinically relevant deletions account for approximately 56% of the abnormalities identified by CMA analysis, with clinically relevant duplications accounting for about 27%, and whole chromosome aneuploidy accounting for about 17% (7).

Genomic architecture has been shown to be a predisposing factor to DNA rearrangements that underlie disease, and it is estimated that 23% of the clinically relevant deletions and duplications identified arise because of flanking low copy repeats (LCRs) (Figure 45-1B and D) (8). Therefore, the majority of clinically relevant deletions and duplications are unique with variable breakpoints (Figure 45-1C). For diagnostic purposes, each gene within the identified deletions or duplications must be evaluated to determine if it is likely to be dosage sensitive, with an estimated 5–10% of genes causing a phenotype when deleted or duplicated (9). Determination of dosage sensitivity relies on review of published data for each gene, or chromosomal region. Nonrecurrent, but clinically recognizable deletion syndromes include

Wolf-Hirschhorn syndrome (WHS) (4p16), Cri du Chat syndrome (5p15), and the 18p and 18q deletions syndromes. These classic syndromes were all initially defined by clinical recognition of the phenotype, with subsequent identification of the genomic alteration based on cytogenetics, and narrowing of a critical region associated with specific phenotypes.

LCRs or segmental duplications (SDs) predispose to mispairing in meiosis, with subsequent deletion or duplication following recombination (10,11) (Figure 45-1A–D; Table 45-1). Classic microdeletion syndromes that are recurrent and LCR mediated include Williams syndrome (7q11.23 deletion), Prader-Willi/Angelman syndromes (15q11.2 deletions), Smith-Magenis syndrome (SMS) (17p11.2 deletions) and DiGeorge/Velocardio-facial syndromes (22q11.2 deletions). There are also several recurrent microdeletion syndromes that have been identified following the increased usage of CMA and these include deletions of 1q21.1, 8p23.1, 15q13.3, 16p11.2, 17q12, and 17q21.3. The 17q21.3 microdeletion syndrome was the first new disorder identified using CMA (12,13), and the features of this syndrome are consistent, such that the phenotype can now be clinically recognized. However, many of these recently identified microdeletion disorders have proven challenging, in that the deletions are often inherited from a mildly affected or phenotypically normal parent, suggesting that these deletions are characterized by marked variable expressivity. Included in this group with unclear phenotypes are the 1q21.1 and 15q13.3 recurrent microdeletions (Table 45-1).

There are several recurrent microduplications that have known phenotypic consequences including duplications of

**FIGURE 45-1** (A) Diagram demonstrates a genomic section with a gene (rectangle) flanked by low copy repeats (LCR1,2) undergoing normal recombination, which maintains the content of the gene with no deletions or duplications. (B) Demonstration of mispairing of the homologous repeats (LCR1,2) resulting in a deletion and a duplication. Following a recombination event within the mispaired repeats, one chromatid has a duplication of the gene, while the other chromatid is deleted for the gene. (C) Demonstration of random breakpoints associated with deletions that are not mediated by low copy repeats. (D) Demonstration of recurrent breakpoints resulting from nonallelic homologous recombination (NAHR) between repeats LCR1 and LCR2, which flank a gene.

TABLE 45-1 Recurrent Reciprocal Copy Number Changes (CNC) and Their Clinical Significance								
Chromosome Bands	Deletions		Duplications		Critical/ Candidate Gene	Approximate Size (Mb)	Approximate Breakpoint (Mb, hg19)

Pathogenic = CNC known to result in clinically significant phenotype, rarely seen in unaffected individuals; Likely pathogenic = newly described CNC, rarely seen in unaffected individuals; Uncertain = associated with a range of phenotypes, also seen in unaffected individuals; Likely benign = few reports being associated with mild phenotype, but a low penetrance, seen at equal frequency in affected and control populations.

TAR, thrombocytopenia-absent radius; HNPP, hereditary neuropathy with liability to pressure palsies; CMT1a, Charcot-Marie-Tooth type 1a; RCAD, renal cysts and diabetes syndrome.

<sup>a</sup>Band changed between hg18 and hg19 build; 16p12.1 in hg18 build.

7q11.23 (reciprocal to the Williams syndrome deletions), 8p23.1, 16p11.2, 17p11.2 (Potocki-Lupski syndrome (PTLS)), 17p12 (Charcot-Marie-Tooth (CMT) associated duplication), 17q12 (*HNF1B* associated duplication), and 22q11.2 (reciprocal to the DiGeorge syndrome (DGS) associated deletion), all of which are associated with LCRs (14) (Table 45-1). Other microduplication syndromes have been reported, but the duplications are often inherited from a normal parent, and there is limited phenotypic data. Further studies are needed to determine if these microduplications are benign variants or pathogenic; these duplications include 1q21.1, 3q29, 15q11.2 (*NIPAI* associated duplication), 16p13.1, 22q11.2 and the Xp22.31 (steroid sulfatase (STS)-associated duplication).

Besides deletions and duplications, there are several other types of chromosome rearrangements that lead to human disease including translocations, inversions, ring chromosomes and isochromosomes (a specific type of deletion/duplication). In this chapter, we also include a discussion of uniparental disomy (UPD), as it occurs via abnormal chromosome segregation. In addition, the increasingly frequent use of single-nucleotide polymorphism (SNP) arrays in the diagnostic laboratory makes identification of UPD increasingly common in clinical practice.

We review the most frequently observed deletions, duplications and translocations to provide access to information on the most common of the myriad of cytogenetic abnormalities. In addition, we present several rare disorders, which provide insights into the mechanisms of cytogenetic disease.

## 45.2 TRANSLOCATIONS

### 45.2.1 Cytogenetically Balanced Translocations

A translocation results from interchange of chromosomal segments between at least two chromosomes. Often, translocations occur between nonhomologous chromosomes (Figure 45-2). Translocations are considered balanced if the transfer of genetic information between the chromosomes is reciprocal, and no genetic material is lost or gained. Robertsonian translocations (discussed later) are associated with a loss of genetic material, but generally are not associated with phenotypic abnormalities. Translocations can be inherited (familial) or *de novo* (newly occurring).

Balanced translocations occur in approximately 1/500–1/600 individuals (15,16). The majority of

**FIGURE 45-2** Pachytene diagram of a hypothetical translocation between chromosomes 7p and 20p is shown. The normal 7 and 20 and derivative 7 and 20 all line up together, with several possible segregation outcomes. If alternate centromeres move into the same gamete, then the resulting fetus would either be normal with respect to chromosomes 7 and 20, or have a balanced rearrangement, similar to the parent. However, if adjacent centromeres move into the same gamete, several types of unbalanced gametes will form. The normal 7 paired with the der(20) will result in monosomy for part of 20p, and trisomy for part of 7p; or if the normal 20 segregates with the der(7), partial trisomy 20p and monosomy 7p results. These latter alternatives, with proper segregation of the different centromeres, but partial monosomy and trisomy for distal segments, are considered Adjacent I segregants. Adjacent 2 segregation occurs when the chromosome 7 and der(7) or 20 and der(20) segregate together, resulting in more profound partial trisomy or monosomy, including the centromeric area. Three to one segregation occurs when three centromeres move into one gamete, with only one chromosome in another. This is a common observation in the recurrent translocation 11;22.

balanced translocation carriers do not have associated clinical problems except decreased fertility and the risk of abnormalities to their offspring as a result of malsegregation of the translocation (Figure 45-2). However, the frequency of apparently balanced translocations, particularly *de novo* rearrangements, is higher in the mentally retarded population than in the newborn population (17–19). The frequency of clinical abnormalities among carriers of *de novo* reciprocal translocations is about 6% (20). In rare cases, balanced translocation carriers manifest features of a recognizable, dominant genetic disease due to interruption of a specific disease gene at the breakpoint of the translocation. Several autosomal dominant and X-linked diseases have been caused by a reciprocal translocation including Duchenne muscular dystrophy (21), neurofibromatosis 1 (22), supravulvar aortic stenosis (23), aniridia (24) and Alagille syndrome (25). CMA has shown that reciprocal translocations in phenotypically abnormal individuals are more likely to be associated with imbalances at the translocation breakpoints that cannot be seen by karyotype analysis (26). Another explanation for the association of congenital anomalies and apparently balanced reciprocal translocations is that the presence of a balanced rearrangement in a parent may be a predisposing factor for UPD in their offspring. This is discussed in some detail in a later section of this chapter.

### 45.2.2 Consequences of and Counseling for Reciprocal Translocations

Balanced translocation carriers are at risk for abnormal chromosomal segregation during meiosis. The consequences include infertility, multiple pregnancy losses, and live-born offspring with multiple congenital malformations as a result of chromosomal imbalance.

During meiosis, homologous chromosomes pair to form a synaptonemal complex. When there is a balanced translocation, all four chromosomes (the two chromosomes involved in the translocation and the two noninvolved) pair to produce a quadrivalent configuration (Figure 45-2). Normal gamete formation relies upon the segregation of alternating centromeres into two daughter cells, producing either a normal gamete or a gamete containing both partners of the balanced translocation. However, if adjacent centromeres segregate together, chromosomally unbalanced gametes are produced (Figure 45-2). For couples with a balanced translocation, abnormal segregations lead to recurrent miscarriages, stillborn offspring, or live-born offspring with multiple congenital abnormalities. Fertilization of a gamete containing adjacent segregants by a normal gamete results in a zygote with partial trisomy (duplication) and partial monosomy (deletion) for the relevant portions of the involved chromosomes. Pregnancy outcome is related to the size and composition of the rearranged chromosomal segments. In some

cases the imbalance is so severe that it results in miscarriage before a pregnancy is recognized. Such early pregnancy losses present clinically as infertility. Most balanced rearrangements are unique (i.e. they are only observed within a given pedigree), making it difficult to provide precise risk figures for each of the meiotic outcomes. If an individual with a balanced translocation was ascertained because of the birth of a chromosomally abnormal child, then it is known that at least one of the unbalanced karyotypes is compatible with life, and the risk for producing a subsequent affected child is high (5–30% by empirical data) with a significant risk for miscarriage or stillbirth (27–29). In cases where the balanced carrier was ascertained in an unbiased fashion (e.g. newborn screening studies) the risk for a chromosomally unbalanced child is lower (1–5%), with a significant risk for miscarriage or stillbirth (30). In this latter group there are many reciprocal translocations whose unbalanced segregants result in a phenotype that is severe and incompatible with life.

### 45.2.3 Recurrent Translocations

Most reciprocal translocations occur uniquely, at apparently random positions throughout the genome, with a few exceptions. To date, at least five recurrent translocations have been described. All these are mediated by repeat sequences within the genome, including both LCRs and palindromic, AT-rich regions that are prone to instability. These recurrent translocations include t(4;8)(p16;p23), t(4;11)(p16.2;p15.4), t(8;12)(p23.1;p13.31), t(8;22)(q24.13;q11.2), and t(11;22)(q23;q11.2).

### 45.2.4 t(11;22) Syndrome

The t(11;22)(q23;q11.2) is the most common, non-Robertsonian, constitutional translocation seen in humans (31–33). Several hundred families with this rearrangement have been described. The translocation appears to be independent of environmental factors and is estimated to have a low rate of mutation based on the paucity of *de novo* cases. In multiple unrelated families the breakpoints on both chromosomes 11 and 22 are tightly clustered (34,35). Further, similar breakpoints in numerous families occur within AT-rich repeat regions on chromosomes 11q23 and 22q11, suggesting genomic instability as the mechanism mediating the rearrangement (36,37). An unexpectedly high rate of *de novo* constitutional t(11;22) translocations in sperm from normal males has been reported, indicating that this translocation originates during meiosis (38).

Carriers of the constitutional t(11;22) are phenotypically normal, but come to attention subsequent to the birth of an abnormal offspring with the derivative chromosome 22 as a supernumerary chromosome, or upon being treated for infertility. Only one type of unbalanced karyotype is seen in live-born offspring in association

with this translocation, 47,XX(Y), +der(22)t(11;22)(q11.2;q23). This unbalanced karyotype is a result of missegregation during meiosis, referred to as 3:1 segregation, to produce a gamete with an extra chromosome (Figure 45-2). Presumably, unbalanced karyotypes with 46 chromosomes and the der(11) or the der(22) are non-viable. The minimal overall recurrence risk of balanced carriers for producing unbalanced offspring is estimated to be 2%. The risk could be as high as 5.6%, if one includes the nonkaryotyped stillborn children who were reported as malformed (32). The spontaneous abortion frequency is 27%. There is apparently no difference in the risk to male versus female carriers but there appears to be an excess of female balanced carriers among the phenotypically normal offspring of females with the t(11;22).

The syndrome associated with the presence of a supernumerary chromosome in the proband is designated the supernumerary der(22)t(11;22) syndrome, +der(22) syndrome, or Emanuel syndrome (OMIM# 609029). The phenotype of individuals with the +der(22) is discussed later in this chapter.

### 45.2.5 Other Recurrent Translocations

The t(4;8)(p16;p23) rearrangement, in the unbalanced form, has been reported multiple times in association with congenital anomalies. It has been shown to result from recombination between the olfactory receptor gene cluster LCRs (39,40). However, for the recurrent t(4;8), the precise breakpoint location has not been determined at nucleotide sequence resolution. Individuals with an unbalanced karyotype containing the der(4) show typical features of the Wolf-Hirschhorn deletion syndrome (41,42), while those with the der(8) show a milder dysmorphic syndrome (39).

The reported cases of the t(4;11)(p16.2;p15.4) have the same breakpoint intervals by CMA, suggesting this is a novel recurrent translocation. The formation of the t(4;11) appears to involve interchromosomal paralogous LCRs of 130 kb in length and 94.7% DNA sequence identity located in olfactory receptor gene clusters (43). The t(4;11) recurrent rearrangements occur within SDs with sequence homology at the breakpoints.

To date, two patients with a der(8)t(8;12)(p23.1;p13.31) have been identified (43). LCR clusters on both 8p23.1 and 12p13.31 that contain a 285 kb region of >94% homology, providing evidence that the translocations likely arose via interchromosomal nonallelic homologous recombination (NAHR). These patients had deletion of 8p23.1 to pter, with triplication of 12p13.31 to pter.

Another recurrent palindrome-mediated rearrangement is the t(8;22)(q24.13;q11.21) (44). Nearly identical palindromic AT-rich repeats on chromosomes 8 and 22 at the translocation breakpoints have been validated in several of the new and previously reported cases.

A syndrome characterized by extremity anomalies, mild dysmorphism and intellectual impairment is caused by 3:1 meiotic segregation of this rearrangement. The affected individuals have 47 chromosomes with a supernumerary der(22)t(8;22). Similar to the t(11;22), polymerase chain reaction (PCR) analysis of sperm DNA from healthy males indicates that the t(8;22) arises *de novo* during gametogenesis in some, but not all, individuals.

### 45.2.6 Robertsonian Translocations

Robertsonian translocations are a specific class of translocations in which two acrocentric chromosomes fuse at their centric ends (45). In humans, chromosomes 13, 14, 15, 21, and 22 are acrocentric, and all of these chromosomes are associated with Robertsonian translocations. The short arms of all of the acrocentric chromosomes contain numerous copies of the genes coding for ribosomal RNA. Because counting the number of centromeres in a metaphase spread assesses chromosome number, individuals with a Robertsonian translocation have 45 chromosomes. The small reciprocal product, which contains the remnants of the short arms of the two fused chromosomes, is usually lost. Loss of the short arms of two acrocentric chromosomes is not deleterious and individuals with this type of rearrangement are generally phenotypically normal. Robertsonian translocation carriers may be at increased risk for having children with abnormalities either because of malsegregation of the translocation chromosome or as a consequence of their increased risk for having offspring with UPD.

### 45.2.7 Counseling for Robertsonian Translocations

As with reciprocal translocation carriers, there is a risk to carriers of balanced Robertsonian translocations for producing unbalanced offspring. In general, Robertsonian translocation carriers are at increased risk for spontaneous abortions (29) and an association has been observed between Robertsonian translocations and male infertility (46). Clinically, the most significant is for carriers of a Robertsonian translocation that involves chromosome 21. These individuals are at risk for producing a child with Down syndrome. Female carriers have approximately a 15% risk for a live-born child with Down syndrome and male carriers have a much lower risk (about 1–2%) (30). In patients with Down syndrome, 4% have a Robertsonian translocation involving chromosome 21. The translocation is familial (inherited) in 25% of these patients and *de novo* in 75% (47). Theoretically, carriers of Robertsonian translocations involving chromosome 13 could produce offspring with trisomy 13 (Patau syndrome), but this is rarely observed. Robertsonian translocations between homologous chromosomes (e.g. 21;21 or 13;13) pose unique problems, since carriers are unable to produce normal gametes.

### 45.3 UNIPARENTAL DISOMY

UPD is the inheritance of a pair of chromosomes (or a portion of a pair) from only one parent (48). UPD is most easily identified by the study of polymorphic loci, which reveals a pattern consistent with the presence of two alleles from the one parent, and the absence of inherited alleles from the other parent. UPD is sometimes associated with clinical abnormalities, and this can occur by two mechanisms: having two copies of a recessive disease gene or absence of an imprinted gene.

Uniparental *isodisomy* (the inheritance of two copies of one homolog from a parent) can be associated with disease when there is a mutant allele for a recessive disorder present on the affected chromosome. In these cases, the patient would present with a homozygous mutation even though only one parent is a disease carrier. The identification of UPD is usually subsequent to the unexpected identification of a homozygous mutation in the patient. This has been observed for several recessively inherited diseases, including cystic fibrosis (49,50) and Bloom syndrome (51).

UPD is also associated with disease through the uniparental inheritance of a region of the genome containing an imprinted gene (see Chapter 10). Imprinted genes are differentially expressed depending on whether they are inherited from the male or female parent (52). In the case of imprinting-associated disease, the UPD can be *isodisomy* or *heterodisomy* (the inheritance of both parental homologs from one parent). The best-studied examples of this phenomenon in humans are Prader-Willi and Angelman syndromes, which are discussed later in this chapter. Both these disorders can be associated with loss of expression of imprinted genes located on chromosome 15q11q13. The loss of gene expression can be caused by deletion of one parental chromosome, or UPD. The absence of a paternal chromosome, due to either maternal UPD (two copies of a maternally inherited chromosome 15 and no copies of the paternally inherited chromosome 15) or a deletion of 15q11q13 on the paternal chromosome leads to the Prader-Willi syndrome (PWS). The absence of a maternal chromosome, due to either paternal UPD or a deletion of 15q11q13 on the maternal chromosome, leads to Angelman syndrome (AS), a clinically distinct syndrome (53,54). Another imprinting disorder is the Russell-Silver syndrome, which is characterized by pre- and postnatal growth retardation, triangular facies, and facial, limb or truncal asymmetry. Imprinted genes on chromosome 7 and chromosome 11 have been associated with this disorder. Maternal UPD for chromosome 7 is seen in about 10% of cases (55). Three imprinted genes within chromosome 7q31 have been identified, and patients with segmental maternal isodisomy of this region have been reported (56). Duplication of maternal genes within 7p11.2-p13 is also associated with this disorder. Therefore, Russell-Silver syndrome appears to be caused by extra copies of maternal genes rather than by

loss of a paternally imprinted gene (57). Russell-Silver syndrome is also associated with imprinted genes located within chromosome 11p15.5. As with the imprinted locus at 15q11q13, the parent of origin determines the clinical presentation, with maternal UPD of 11p15 associated with Russell-Silver syndrome, and paternal UPD associated with Beckwith-Wiedemann syndrome, an overgrowth disorder.

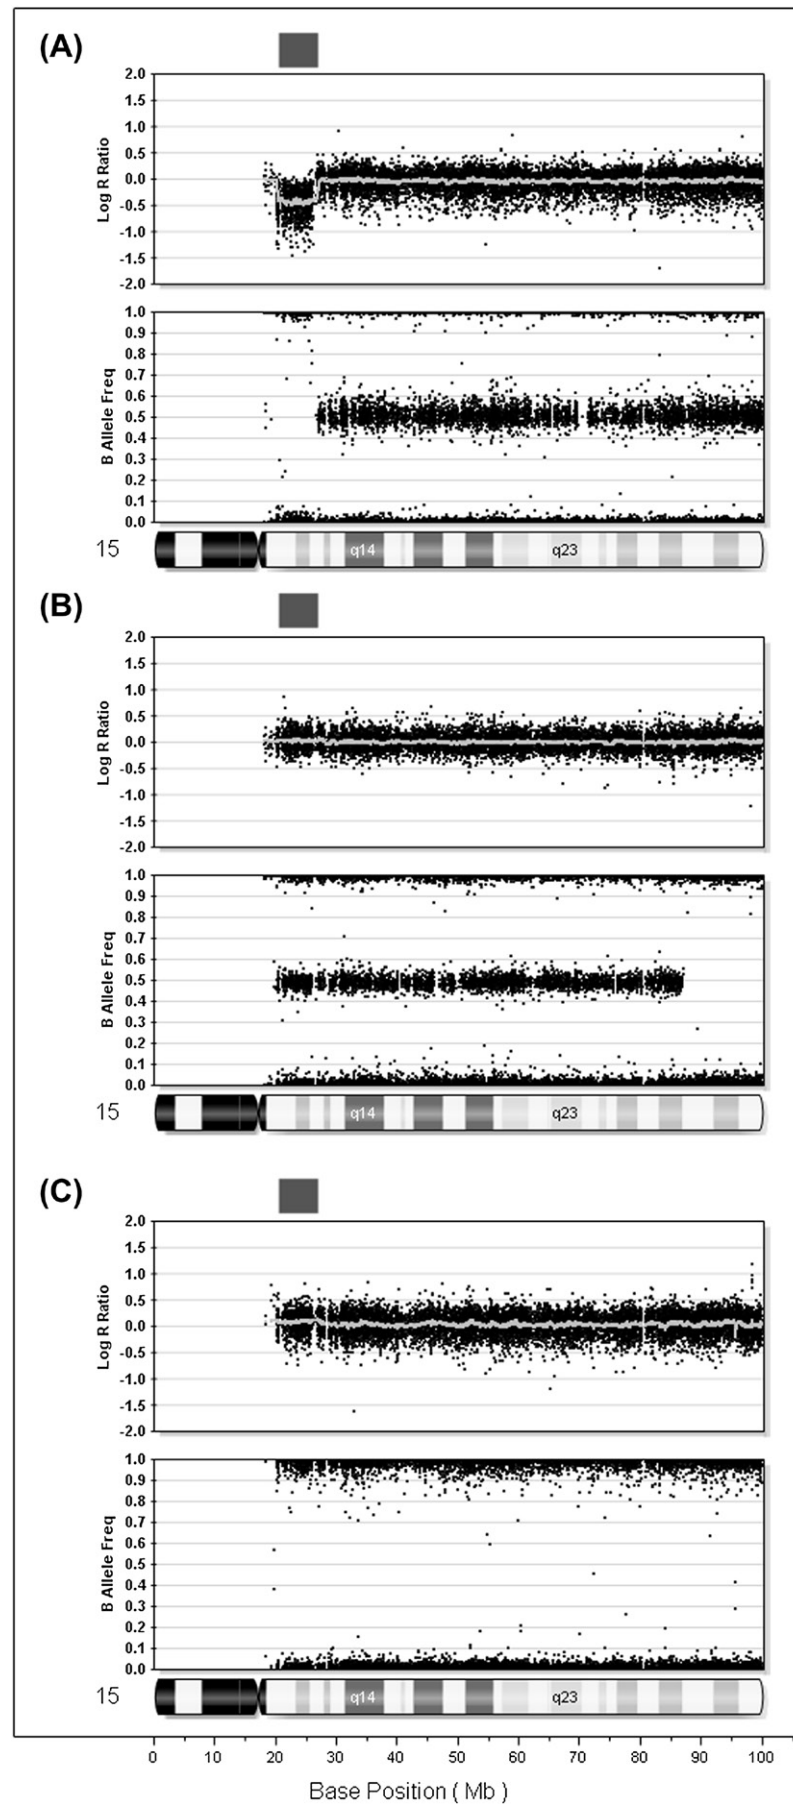

UPD often involves an entire chromosome, and may have originated through a trisomy rescue or monosomy rescue (55). Utilization of SNP arrays has increased our ability to detect UPD, and in some cases, examination of the genotyping patterns on the SNP arrays allows detection of the mechanism by which the UPD has occurred (Figure 45-3B and C) (58).

An association has been observed between UPD and inherited or *de novo* Robertsonian translocations. Malsegregation of familial Robertsonian translocations can result in UPD for one of the chromosomes involved in the translocation in multiple cases (59–62). UPD has also been observed in association with *de novo* Robertsonian translocations (63–67). Among the acrocentric chromosomes, UPD for chromosomes 13, 21 or 22 does not appear to be associated with phenotypic abnormalities, while UPD for chromosome 15 is associated with Prader-Willi or Angelman syndromes and UPD for chromosome 14 has been associated with multiple abnormalities (68).

### 45.4 DELETION

Loss or deletion of a chromosomal segment potentially results in an individual having only one copy of a portion of the genome, leading to hemizyosity for one or more loci. A deletion may be terminal (at the end of the chromosome) or it may be interstitial (within the chromosome). The clinical consequences of deletions depend on the size of the deleted segment and the number and function of the genes involved in the deletion. Deletions can either occur *de novo* or be inherited from a parent. Deletions may also result from malsegregation of a parental balanced translocation, or other chromosomal rearrangements. Translocation-mediated deletions are generally accompanied by partial trisomy of another chromosomal region, resulting in partial duplication accompanying the deletion. There have been isolated reports of deletions of many regions of the genome. As described earlier, some deletions occur sporadically, with only rare cases of similar breakpoints, while other deletions are recurrent. As discussed in the introduction, some of these deletions were originally identified based on clinical phenotypes and karyotypic analysis, while others were identified via CMA, with subsequent comparison of the phenotypes of patients with the deletion or duplication.

Genomic deletion disorders are generally characterized clinically by abnormalities in multiple systems. In

some cases, disorders that were originally associated with deletions were subsequently found to be caused by a single gene mapping within the deletion (e.g. Alagille (69) and Rubenstein-Taybi syndromes (70)). Even for the disorders caused by loss of multiple genes, it is unlikely that all the genes that map within the deleted segment play an important role in the causation of the major features of the phenotype. The fine mapping that is possible using chromosomal microarrays has brought us a long way toward defining the genes that cause an abnormal phenotype when deleted (haploinsufficient genes), while genes that are commonly found deleted in control individuals do not appear to be associated with clinical abnormalities (haplosufficient genes). Deletions that have been associated with clinically recognizable syndromes are discussed below. A list of recurrent chromosomal deletions is given in Table 45-1.

### 45.4.1 Chromosome 1p36 Deletion Syndrome

Early case reports described patients with deletions of 1p36 (94,95); however, it was not described as a clinically recognizable syndrome until sufficient numbers of patients with deletions were identified (MIM# 607872) (96). The 1p36 deletion is thought to be the most common terminal deletion, with a frequency of 1/5000–1/10,000 live births (97). There is a wide range of deletion sizes and no common breakpoint.

**45.4.1.1 Clinical Presentation.** Affected individuals have a characteristic facies consisting of midface hypoplasia, frontal bossing, deep set eyes, long philtrum, and pointed chin. Late closure of anterior fontanel, structural brain malformations including ventriculomegaly, cardiac defects, seizures, hypotonia, hearing loss, and vision problems are noted in most individuals with this deletion. Skeletal and genitourinary abnormalities are reported frequently as well. Developmental delay, poor to absent speech and intellectual disability is present in every individual with variable severity (97–99). Recently, a few cases with PWS-like features including hypotonia, obesity, and cognitive delays

have been associated with the 1p36 deletion (100,101). More than 10 cases of 1p36 deletion syndrome have been diagnosed prenatally. The most common prenatal findings are ventriculomegaly, midface hypoplasia and heart defects (102,103).

#### 45.4.1.2 Cytogenetics and Molecular Cytogenetics.

The 1p36 deletion syndrome is associated with pure terminal deletions, interstitial deletions and complex rearrangements. More than half the cases are *de novo* terminal deletions, one-quarter are interstitial deletions, and about 3% of cases are due to malsegregation of a balanced parental translocation. The size of the deletion is variable, ranging from 0.5 Mb to greater than 10 Mb, with no clear correlation between the extent of the deletion and severity of the features (99).

### 45.4.2 1q21.1 Microdeletion

The use of CMA analysis in individuals with intellectual disability, multiple congenital anomalies and developmental delay has resulted in the diagnosis of several new genomic disorders including the 1q21.1 deletion syndrome (MIM# 612474) (104). The 1q21.1 deletion is a recurrent microdeletion, which is not visible by standard chromosome karyotype analysis (104) (Table 45-1). Since its discovery, the 1q21.1 deletion has been associated with a variety of features (see later); however, the deletion is also seen in clinically unaffected individuals. This recurrent microdeletion therefore presents variable expressivity and incomplete penetrance.

**45.4.2.1 Clinical Presentation.** The 1q21.1 deletion syndrome (OMIM# 612474) does not present as a clinically recognizable syndrome; however, approximately half the individuals with this deletion have microcephaly, mild dysmorphic features and intellectual disability. This deletion has been associated with a variety of phenotypes including microcephaly, schizophrenia, epilepsy, cardiac disease, genitourinary abnormalities, cataract, and hypotonia (72,73,105). The 1q21.1 deletion has been found to be *de novo*, or inherited from a clinically unaffected or mildly affected parent. The variable expressivity, wide range of clinical findings, and inheritance from

**FIGURE 45-3** Data from the utilization of a genome-wide SNP array demonstrating diagnosis of genomic abnormalities. In each panel, the data are presented using two transformations, the  $\log_2 R$  ratio (top) and B allele frequency (bottom). For each panel, each SNP is represented by a dot, and the data are displayed along the length of the chromosome, with the ideogram underneath the B allele frequency plot. The  $\log_2 R$  ratio indicates the intensity of the signal at each SNP, compared to a set of “control” individuals, who presumably have two copies at that locus. Therefore if the subject has two copies, the SNPs should plot out at 0 [ $\log_2(2/2) = \log_2(1) = 0$ ]. Deletions are seen as negative values, while duplications are seen as positive values. The genotype of each SNP is also determined, and transformed into a B allele frequency. Each SNP is bi-allelic, with each allele being either an “A” or “B”. The B allele frequencies are then determined by the number of B alleles present. A genotype of AA has a B allele frequency of 0%, AB has a B allele frequency of 50%, and BB has a B allele frequency of 100%. Panel A shows a deletion of chromosome 15q11q13. Note the decreased  $\log_2 R$  ratio where the intensity drops, as well as the lack of heterozygotes shown in the B allele frequency track. This is a deletion associated with Prader-Willi or Angelman syndrome. Panel B demonstrates a normal  $\log_2 R$  ratio across all of chromosome 15, with a region of homozygosity toward the q terminus. This patient has uniparental disomy for chromosome 15, with heterodisomy near the centromere (presence of AB genotypes), and isodisomy near the telomere (absence of AB genotypes). This transition of hetero/isodisomy marks a meiotic crossover (372). Panel C demonstrates a patient with uniparental isodisomy for chromosome 15. Note the normal  $\log_2 R$  ratio, but complete lack of heterozygosity across the entire chromosome. The critical region for Prader-Willi or Angelman syndrome is noted by a dark gray rectangle above the array plots.

apparently unaffected parents poses a significant counseling dilemma for this syndrome.

#### 45.4.2.2 Cytogenetics and Molecular Cytogenetics.

The 1q21.1 microdeletion is a recurrent deletion associated with LCRs. The minimum deletion size is 1.35 Mb, which includes at least nine genes, including PRKAB2, FMO5, CHD1L, BCL9, ACP6, GJA5, GJA8, GPR8 9B and a paralog of the HYDIN (HYDIN2) gene. Mutations in HYDIN are known to be involved in hydrocephalus, and HYDIN2 has been suggested as a candidate for the microcephaly associated with 1q21 deletions (72). Note that there is a second, distinct, microdeletion syndrome within 1q21.1 associated with the thrombocytopenia, absent radius (TAR) syndrome, which is distinct from and is located proximal to the 1q21.1 syndrome described here (71).

### 45.4.3 Wolf-Hirschhorn Syndrome (WHS; 4p-)

Partial monosomy of the short arm of chromosome 4 is associated with a clinically distinct syndrome characterized by recognizable facial dysmorphism in combination with marked growth retardation of prenatal onset and severe mental deficiency (106–108). The true incidence of this syndrome is not known, with estimated rates of 1/50,000–1/95,896 (109–111). WHS was originally defined by the clinical phenotype, and subsequently found to be caused by deletions of chromosome 4p. In the majority of cases, the breakpoints of the deletions are nonrecurrent; however, recurrent unbalanced translocations involving chromosome 4p16 have been identified (39,43).

**45.4.3.1 Clinical Presentation.** The distinctive face has been called the “Greek helmet” facies, characterized by microcephaly and frontal bossing with a high frontal hairline; prominent glabella, ocular hypertelorism; proptosis due to hypoplasia of the orbital ridges; slanted palpebral fissures and epicanthal folds; a broad and beaked nose with a large, prominent bridge and shallow septum. Strabismus is a common finding. The ears are low-set, large, and simple, and are commonly seen with preauricular pits or tags. The mouth is downturned, with a short upper lip and philtrum, and micrognathia is present. Closure defects are common including cleft lip and/or palate in about 15% of patients, coloboma of the iris, cardiac septal defects (present in more than 50% of patients and a leading cause of mortality); and genital anomalies such as hypospadias, scrotal hypoplasia, cryptorchidism or testicular hypoplasia. Low birth weight, growth retardation and failure to thrive are commonly reported.

Intellectual disability is usually severe, with IQs below 20. Seizures are frequent and usually begin within the first two years of life. Heart disease and a high susceptibility to infection are frequently the cause of death.

Postnatal mortality has been reported as high, with one-third of patients dying during the first year of life; however, more recent analyses have noted that risk of death is significantly skewed toward patients with larger deletions (111).

#### 45.4.3.2 Cytogenetics and Molecular Cytogenetics.

WHS is caused by partial deletion of the short arm of chromosome 4 (4p-). The critical region for this disorder (Wolf-Hirschhorn critical region, WHCR) is located approximately 2 Mb from the telomere, within band 4p16.3 (112). Approximately 45–50% of deletions are associated with an unbalanced translocation, and the remaining patients have *de novo* pure terminal or interstitial deletions (113). The size of the deleted region can vary greatly among patients, although such variations do not apparently result in important differences in phenotype, suggesting that there are relatively few genes responsible for the major characteristics of this syndrome (108); however, the high frequency of unbalanced translocations associated with this disorder complicates the ability to determine the genotype/phenotype relationship. Two recurrent translocations have been associated with WHS (der(4)t(4;8)(4p16.3;8p23.1) and der(4)(4;11)(p16.2;p15.4)).

A number of patients have been described with very subtle translocations and deletions. In many of these cases, cytogenetic studies were normal, but a small deletion within 4p16 was detectable by molecular analysis or CMA (114). The presence of phenotypic features of WHS and a normal karyotype warrant further molecular investigation of the patient, as many of the translocations associated with Wolf-Hirschhorn may be cryptic. If a submicroscopic deletion is detected by microarray testing, analysis of parental chromosomes by molecular cytogenetic techniques (fluorescence in situ hybridization (FISH)) is of primary importance, since one of the parents could carry a cryptic translocation. If this is the case, prenatal diagnosis for future pregnancies could be offered.

Analysis of the deletions seen in patients with WHS has led to the identification of a 165 kb critical region within 4p16.3 (115). At least nine independent putative genes have been identified within this region. A novel developmental gene, *WHSC1*, maps in the distal part of the WHS critical region (116,117). A second critical region (WHSCR2), located 300–600 kb distal to *WHSC1*, has been described. Deletions of WHSCR2 have been associated with milder clinical features. WHSCR2 contains the *LETM1* gene, which is suggested to be associated with the seizure phenotype (41).

Submicroscopic deletions of 4p16.3 have also been found in patients with the Pitt-Rogers-Danks syndrome. The critical regions for the deletions in WHS and the Pitt-Rogers-Danks syndromes have been shown to be overlapping and may represent a clinical spectrum of the same disorder (115,117).

#### 45.4.4 Cri du Chat Syndrome (5p-)

Partial deletion of the short arm of chromosome 5 results in the Cri du Chat syndrome, which was first described in 1963 (118). The syndrome is named because it is associated with a laryngeal defect, which causes a distinctive cry resembling the mewing of a cat. The incidence has been reported to range from 1/15,000 to 1/50,000 newborns (110,119). This syndrome was originally defined by the clinical phenotype, and subsequently shown to be caused by deletions of chromosome 5p. The breakpoints of the deletions are nonrecurrent and not associated with LCRs.

**45.4.4.1 Clinical Presentation.** Patients present in the newborn period with low birth weight, the characteristic high-pitched, catlike cry and craniofacial dysmorphism, consisting of microcephaly, a round (moonlike) face, hypertelorism, epicanthal folds and broad nasal bridge (119,120). Most patients demonstrate hypotonia, and strabismus is common. About 1/3 of patients demonstrate variable types of heart disease.

The catlike cry disappears over the first year and development is severely delayed. Head control is attained at about 1 year, sitting occurs at 2 years and walking begins at 4 years. Speech development is particularly slow. Mortality is about 10% in the first year of life, but it improves for patients beyond this age, with reports of individuals living into their fifties (121). There is a report of an intellectually disabled woman with the Cri du Chat syndrome and an interstitial deletion of 5p who delivered a similarly affected daughter (122). Intellectual disability is usually severe with IQs below 50 in infants and below 20 in adults (123). Early intensive programs of special education have been beneficial, resulting in social and psychomotor development at the level of a 5- to 6-year-old child (121,124–127).

**45.4.4.2 Cytogenetics and Molecular Cytogenetics.** The Cri du Chat syndrome results from *de novo* deletions of 5p in 90% of patients, *de novo* unbalanced translocations in 5% of patients, and missegregation of familial translocations in 5% of patients (121). The extent of the deletion in patients with features of the Cri du Chat syndrome varies widely, but critical chromosomal regions for specific features of the syndrome have been identified. CMA has been used to map DNA copy number differences in 94 patients with Cri du Chat (128), allowing for genotype–phenotype correlations and localization of several clinical features to specific genomic regions. The characteristic cry localizes to a 1.5 Mb region in distal 5p15.31, while speech delay localizes to an approximately 3 Mb region of 5p15.33–5p15.32. Dysmorphic facial features localized to a 2.4 Mb region of 5p15.31–p15.2. The severity of developmental delay was correlated to the size of the deletion and its location in all cases with an isolated 5p deletion. A few genes associated with clinical phenotypes have been identified within the critical region

for Cri du Chat. One such gene is the telomerase reverse transcriptase or *TERT* gene on 5p15.33. Inherited haploinsufficiency for *TERT* results in progressive telomere shortening and autosomal dominant dyskeratosis congenita (DC), characterized by progressive bone marrow failure, nail dystrophy, abnormal skin pigmentation and mucosal leukoplakia. DC is not generally diagnosed in the Cri du Chat syndrome, and there is evidence that the DC phenotype requires several generations of telomere shortening, as could be seen with an inherited, dominant mutation (129). The key genes associated with the phenotypes seen in Cri du Chat syndrome have not yet been identified; however, analysis of transcripts within critical regions is leading to identification of candidate genes for specific features, such as a possible role for Delta-catenin in intellectual disability (130).

#### 45.4.5 Williams-Beuren Syndrome

Williams-Beuren syndrome (WBS) is also referred to as Williams syndrome (MIM# 194050). The clinical features of this syndrome were described in the 1960s (131,132) and in 1993 the genetic basis of this disorder was identified to be a microdeletion on chromosome 7q11.23 involving the elastin gene (133). The estimated frequency of this disorder is 1/7500–1/20,000 live births (23,134,135). This is a recurrent microdeletion, with a common deletion seen in most patients.

**45.4.5.1 Clinical Presentation.** WBS is characterized by cardiovascular defects, recognizable facial features, idiopathic infantile hypercalcemia, connective tissue anomalies, intellectual disability and an outgoing, highly social personality (reviewed in (136)). Patients may present at birth with cardiovascular disease (supravalvular aortic stenosis in 70% of patients and peripheral pulmonary stenosis in 27%), and the syndromic nature of the disorder may go unrecognized in the newborn period (135). Failure to thrive is a common feature during infancy. The characteristic facial features include a broad forehead, medial eyebrow flare, periorbital fullness, strabismus, stellate iris pattern, flat nasal bridge, malar flattening, full cheeks and lips, a long smooth philtrum, pointed chin and wide mouth. Endocrine features of hypercalcemia, hypercalciuria, hypothyroidism and early puberty are frequent. Connective tissue abnormalities are common and include umbilical hernia, rectal prolapse, lax joints or contractures. Individuals with WBS have some degree of intellectual disability, with severe limitations in visuospatial construction skills (deficit in the ability to visualize objects as a set of parts); however, patients usually show exceptional language abilities. Hearing and vision abnormalities are common and early intervention for these is crucial to optimize learning. Many adults tend to experience notable anxiety and neuropsychiatric conditions (reviewed in (136)), and hypertension is common among older individuals (137). The American

Academy of Pediatrics has published management guidelines for individuals with WBS (138).

#### 45.4.5.2 Cytogenetics and Molecular Cytogenetics.

WBS is a true contiguous gene deletion syndrome (139). The majority of the deletions associated with WBS are recurrent deletions mediated by LCRs. An inversion polymorphism on chromosome 7 is seen in only 6% of the general population, while up to 30% of the parents of individuals with WBS are found to carry an inversion polymorphism on chromosome 7, which suggests the inversion predisposes to the deletion (140,141). The commonly deleted region in patients with Williams syndrome is about 1.5 Mb in size and contains 25 genes including ELN (associated with cardiovascular and connective tissue phenotypes), LIMK1 (associated with impaired visual motor integration), and BAZ1B (associated with hypercalcemia) (142–144). A slightly larger, overlapping deletion of 1.8 Mb is seen in 5% of patients (141). A few individuals have atypical, nonrecurrent, deletions. In these individuals, the phenotype depends on the size and genomic content of the deletions. For example, individuals with deletions that do not include the GTF2I gene do not have intellectual disability (76,144).

### 45.4.6 8p23.1 Microdeletion

Terminal deletions, recurrent interstitial deletions, and complex rearrangements involving chromosome band 8p23.1 have been reported with congenital heart defect, diaphragmatic hernia, microcephaly, and intellectual disability (reviewed in (77)). The genomic architecture of chromosome band 8p23.1 includes clusters of olfactory receptor genes, which predispose this region to various genomic alterations including deletions, duplications, and translocations (145). Only the recurrent deletions of 8p23.1 are discussed here.

**45.4.6.1 Clinical Presentation.** Structural cardiovascular defects with or without conduction defects are observed in more than 60% of the individuals with the recurrent interstitial 8p23.1 deletion. These include atrial and ventricular septal defects, double outlet right ventricle, dextrocardia, pulmonary stenosis, and hypoplastic left heart (146,147). Congenital diaphragmatic hernia is seen in ~20% individuals with this deletion (148). Intellectual disability, seizures and aggressive behavior are observed frequently (149). Prenatal diagnosis of the 8p23.1 deletion has been made in at least four cases referred for complex heart defects (150).

#### 45.4.6.2 Cytogenetics and Molecular Cytogenetics.

The size of the 8p23.1 deletion ranges from 2.95 to 6 Mb and this deletion is mediated by LCRs. All the deletions identified to date have been reported to be *de novo*. Haploinsufficiency of GATA4 is thought to result in the heart defect; however, the severity of the condition is greater in patients with this contiguous

deletion as compared to patients with point mutations in GATA4 (151,152). Dosage effects of other genes in the region (e.g. SOX7) are thought to play a role in the severity of the cardiac phenotypes. Of note, there are multiple benign CNVs with the cytogenetic band 8p23.1, which are distinct from this GATA4-containing deletion (see Table 45-1 for breakpoints); therefore, deletions within chromosome band 8p23.1 should be interpreted with caution.

### 45.4.7 Langer-Giedion Syndrome (Trichorhinophalangeal Syndrome Type II)

The Langer-Giedion syndrome, or trichorhinophalangeal syndrome (TRPS) type II was first described clinically and subsequently found to be associated with interstitial deletion of the long arm of chromosome 8 (153). The deletion breakpoints in the Langer-Giedion syndrome are of variable sizes and are nonrecurrent.

**45.4.7.1 Clinical Presentation.** The Langer-Giedion syndrome is one of three forms of TRPS. TRPS II is characterized by multiple cartilaginous exostoses in combination with the clinical features of TRPS type I. TRPS II is characterized by sparse scalp hair, large and laterally protruding ears, bushy eyebrows that are sometimes thinning laterally, broad nasal bridge and bulbous nose, an elongated upper lip, and thin upper vermilion border. Malocclusion, mandibular retrognathia and dental abnormalities are common. There is frequently marked laxity of the skin in infancy and early childhood, which diminishes with age. Brittle nails and multiple nevi are seen frequently. Patients have winged scapulae and short stature of postnatal onset. Multiple cartilaginous exostoses are a defining feature of the disorder. The exostoses may appear in the first year, but may not develop until the fifth year, and they usually increase in size and number until skeletal maturation. There is considerable variability of intelligence and while mild to moderate intellectual disability has been seen in many patients, it does not appear to be a constant feature of the disorder (154). The third form of TRPS (TRPS III) is the most severe and shows the same dysmorphic features as TRPS I, with more severe shortening of all phalanges and metacarpals, short stature (<2 SD) and other skeletal alterations that have been described (155).

#### 45.4.7.2 Cytogenetics and Molecular Cytogenetics.

In 1980, Buhler et al. reported a girl with a terminal deletion of chromosome 8q (del(8)(q24)) with features of Langer-Giedion syndrome. Since that time, deletions or other rearrangements involving 8q24 have been identified in a high percentage of patients (153,156). The deletions are of variable sizes, and most patients with intellectual disability have larger deletions, suggesting that there is a correlation between the size of the deletions and the variable clinical features (157). All deletions associated with TRPS II include both the

TRPS1 gene and the exostosin 1 (EXT1) gene. TRPS1 is a zinc finger transcription factor gene that represses transcription (158,159) and EXT1 catalyzes an essential factor in a signal transduction cascade for regulation of chondrocyte differentiation, ossification, and apoptosis (160).

#### 45.4.8 9q Subtelomeric Deletion (9q-, Kleeftstra Syndrome)

The 9q- syndrome was first described in 2004 following clinical utilization of a FISH-based subtelomere assay as a screen for chromosomal differences in patients with intellectual disability (161–164). A translocation involving interruption of the *EHMT1* gene was instructive in identifying a critical gene responsible for the 9q subtelomere phenotype (165,166). The breakpoints of this terminal deletion syndrome are variable (166).

**45.4.8.1 Clinical Presentation.** Kleeftstra syndrome (MIM# 610253) is characterized by intellectual disability, childhood hypotonia, and a characteristic facial appearance, with some features such as congenital heart disease, renal defects, microcephaly, epilepsy, obesity and behavioral problems occurring in a smaller percentage (165–169). Patients present in the newborn period with hypotonia and delayed early milestones including head control (170). Patients have a characteristic facial dysmorphism with microcephaly or relative microcephaly. Stature is generally short and congenital heart disease is seen in about 50% of patients studied, with conotruncal malformations being the most common. Oculomotor abnormalities included amblyopia, esotropia, divergent strabismus, exotropia, bilateral hypermetropia and convergent squint. There are also abnormalities of the ears, hands and feet, and abnormalities of connective tissue were noted in 50% of the patients (168). All patients demonstrate motor and developmental delay, with seizures described in 40% of patients and behavior problems in about 50%. Behavior problems can include food-seeking behavior leading to obesity, autistic features, hyperactivity, and sleep disturbances.

**45.4.8.2 Cytogenetics and Molecular Cytogenetics.** Cytogenetically visible deletions of the long arm of chromosome 9 are very rare, suggesting that these larger deletions are likely lethal during development (171,172). The 9q deletions have been found to be isolated deletions (70%) or derived from rearrangement with another chromosome (30%) (167–169). Molecular mapping of the deletion breakpoints in patients has demonstrated deletions from 380kb to more than 3Mb (167,173). The identification of a patient with a balanced translocation (t(X:9)(p11.23;q34.3)) and the clinical features of the 9q- deletion syndrome lead to the recognition that haploinsufficiency of the Euchromatic histone-lysine N-methyltransferase 1 (*EHMT1*) gene is the likely cause for the phenotype of this disorder (165). There are repeated regions within 9q, but there is not a common deletion size seen in patients.

#### 45.4.9 15q11.2q13.1 Microdeletion Syndromes

There are two distinct disorders associated with interstitial deletions of proximal chromosome 15q. These are the Prader-Willi and Angelman syndromes. The deleted regions in these two clinically distinct conditions are often overlapping, although it has been determined that PWS results when the deletion is on the paternally inherited chromosome, while AS results from deletion on the maternally derived chromosome. These disorders highlight the importance of imprinting in the etiology of human disease. The deletions in this disorder occur between LCRs, and this is a recurrent deletion (Figure 45-3A) (79). The repeats in this region also mediate the formation of the supernumerary inverted duplication of 15q, discussed later in this chapter.

##### 45.4.9.1 Prader-Willi Syndrome.

**45.4.9.1.1 Clinical Presentation.** PWS is characterized by severe muscular hypotonia, poor suck, and hypogonadism in the neonatal period. Decreased fetal activity has been documented and serves as a prenatal indication to pursue cytogenetic and molecular studies in the neonatal period. During the second year poor feeding is followed by hyperphagia leading to obesity. PWS patients gain weight even when subjected to restricted diets. Patients have mild to moderate intellectual disability, behavioral disorders and characteristic facial features including almond shaped eyes, narrow bitemporal diameter, upslanting palpebral fissures and strabismus. Additional clinical features include short stature, small hands and feet and in about 75% of patients, fair hair and skin color as compared to other family members (174,175). Adults frequently suffer from diabetes and cardiac disease, secondary to weight gain. PWS occurs with an estimated incidence of 1/10,000–1/20,000 live births (176).

**45.4.9.1.2 Cytogenetics and Molecular Cytogenetics.** PWS is caused by the lack of expression of paternal genes from chromosome 15q11.2q13.1 and by three main mechanisms: (1) 15q microdeletions (70–75%), (2) maternal UPD for chromosome 15 (20–25%), and (3) abnormalities of imprinting (2–4%). Deletions of 15q11.2q13 were first described in four patients with PWS in 1981 (177). The majority of deletions are sporadic, *de novo* deletions, mediated by the repeat structure in the 15q11.2q13 region. In all PWS patients studied, the deletion of chromosome 15 occurs on the paternally inherited chromosome (178–180). This unusual finding led to studies of the parental origin of chromosome 15q11.2q13 in chromosomally normal PWS patients. These studies demonstrated that a number of patients had UPD for chromosome 15 (181). In a small percentage of cases, abnormalities in the imprinting process occur, such that all patterns of methylation are altered on the paternal chromosome and hence imprinting balance is abnormal (182). Finally, a few patients have been identified who have apparently balanced translocations with no evidence for deletion (183,184).

The genetic findings in PWS patients suggest that loss of the paternal 15q11.2q13 region, whether by deletion or maternal UPD, causes PWS syndrome. Most cases result from a deletion of 5–7 Mb, which contains a number of imprinted and nonimprinted genes. There are five paternal-only protein-coding genes within the PWS critical region (*MKRN3*, *MAGEL2*, *NECDIN*, *C15ORF2*, and *SNURF-SNRPN*), and a family of paternal-only-expressed snoRNA genes (*HBII-346*, *HBII-13*, *HBII-438*, *HBII-85* and *HBII-52*). While no single genetic alteration has been found that can cause all of the features of PWS, there is evidence for a critical region that includes only the *HBII-85* snoRNA gene (185). *SNRPN* (small nuclear ribonucleoprotein polypeptide N) has been a leading candidate for the PWS disease gene; however, it is not sufficient to cause the disease based on patients with interruption of *SNRPN* who do not demonstrate the full phenotype (183). It is most likely that PWS is caused by loss of more than one gene.

Diagnosis of PWS can be carried out by a combination of molecular studies, CMA, or both. Parent-specific imprinting differences can be detected at the DNA level by examination of the methylation pattern of specific regions of DNA, which is diagnostic in the majority of PWS patients (i.e. those due to deletion, UPD or imprinting center mutations). If a maternal-only pattern of methylation is revealed, the diagnosis of PWS can be confirmed, but further studies are needed to determine the molecular class of the mutation (deletion, UPD or imprinting center mutation).

Recurrence risks for PWS vary with the molecular mechanism identified. Recurrence is low in the case of *de novo* deletions and UPD. However, multiple familial cases have been identified in which there is an imprinting center defect (182) or balanced chromosomal rearrangement (186,187).

#### 45.4.9.2 Angelman Syndrome.

**45.4.9.2.1 Clinical Presentation.** Features of AS include severe motor and intellectual disability, ataxic gait, hypotonia, epilepsy, absence of speech, microcephaly, and a large prominent mandible with open-mouthed expression. Patients are reported to have a happy disposition and demonstrate bursts of excessive, inappropriate laughter. Seizures are a pronounced feature of AS, and have a characteristic EEG pattern. This rhythmic 2–3 Hz high-amplitude delta wave activity is predominantly over the frontal regions, and 3–4 Hz spikes tend to be found more posteriorly. These patterns are not encountered in PWS, in which seizures are not typical (188). The frequency of AS is estimated at 1/15,000.

**45.4.9.2.2 Cytogenetics and Molecular Cytogenetics.** Like PWS, the genetic etiology of AS is complex and is dependent on the parent of origin of the genetic defect. AS is caused by the lack of expression of maternal genes from chromosome 15q11.2q13.1 and is caused by four main mechanisms: (1) 15q microdeletions (70–75%), (2) paternal UPD for chromosome 15 (3–5%), (3) abnormalities of imprinting (4–6%), and

(4) mutation of the *UBE3A* gene (4–6%). Approximately 60% of patients with AS have a cytogenetically detectable deletion of 15q11.2q13 that is identical to that seen in association with PWS. Another 10–15% have a normal karyotype, but a submicroscopic deletion is detectable by FISH (189). In 1994, the *UBE3A* gene (E6-AP ubiquitin-protein ligase) was mapped to 15q11.2q13 within the deletion critical region for AS. Studies demonstrated that *UBE3A* is imprinted in some parts of the brain and, therefore, maternally inherited mutations would be expected to result in phenotypic abnormalities, consistent with findings in AS. *UBE3A* is not imprinted in lymphoblastoid and fibroblast cells (190). Four to six percent of Angelman patients have mutations in *UBE3A*, and these mutations have been found to account for a significant proportion of familial cases (191). The *UBE3A* gene functions to catalyze the transfer of ubiquitin to substrates, which are then targeted for degradation by the proteasome. This is the first member of the ubiquitination pathway to be implicated in a genetic disease; however, the mechanism by which loss of function of *UBE3A* leads to AS is not understood. As in the PWS, there is also a class of Angelman patients (4–6%) who have imprinting mutations. That is, there is a defect in the imprinting center such that the affected chromosome is incapable of becoming appropriately imprinted, resulting in failure to express maternal-only genes. In some cases, these mutations are caused by small deletions and, in others, the precise defect has not been identified (191). In addition to all the mechanisms of mutations leading to AS discussed earlier, there are still 10–14% of patients in whom no molecular defect has yet been found.

The most straightforward diagnostic test for AS is analysis of methylation status, which can detect imprinting differences. If methylation analysis is shown to be abnormal, the molecular class of the abnormality can be determined in order to provide accurate counseling information (low recurrence for large deletions and UPD, higher for small deletions that affect the imprinting center). If methylation studies are normal, point mutations in the *UBE3A* gene can be investigated by mutation analysis.

#### 45.4.10 15q13.3 Microdeletion

The 15q13.3 deletion is a newly characterized recurrent deletion syndrome (192) (MIM# 612001). The deletion was identified by using CMA in a cohort of individuals with intellectual disability, which revealed a 1.5 Mb deletion that occurs between two repeat clusters (BP4 and BP5) within chromosome band 15q13.3. Variable expressivity and incomplete penetrance is observed in this syndrome.

**45.4.10.1 Clinical Presentation.** The features associated with this deletion are highly variable, and include intellectual disability, seizures, autism spectrum disorder, developmental delay, mildly dysmorphic features and schizophrenia (105,192–196). More than 120 cases of

15q13.3 deletion have been reported, and when parental testing was available, most of these deletions were seen to be inherited from an unaffected or mildly affected parent. Three individuals with more severe phenotypes were found to have homozygous deletions within 15q13.3, and presented with profound intellectual disability, hypotonia, eye abnormalities and refractile seizures (197,198).

**45.4.10.2 Cytogenetics and Molecular Cytogenetics.** The 15q13.3 deletion is an LCR-mediated recurrent deletion (192). The deletion size ranges from 1.5 to 2 Mb and the critical region contains 7 genes including CHRNA7, ARHGAP11B, MTMR15, MTMR10, TRPM1, KLF13, and OTUD7A. The 15q13.3 deletion is usually inherited (57–90%) from a mildly affected or unaffected parent (195,199). The critical region for this deletion syndrome is flanked by multiple SDs, and several distinct deletions within chromosome band 15q13.3 that do not involve the critical genes have been shown to be present in normal controls (benign CNVs).

#### 45.4.11 16p13.1 Microdeletion

Deletions of 16p13.1 were first identified using CMA analysis in 2007 (200). The 16p13.1 microdeletion is a recurrent deletion.

**45.4.11.1 Clinical Presentation.** The 16p13.1 microdeletion is characterized by extreme variability of phenotypes. Deletion of 16p13.1 has been reported in individuals with autism and intellectual disability (200). Deletions of 16p13.1 have also been associated with developmental delay, schizophrenia and epilepsy (201–204). Other reported features include microcephaly, mild dysmorphic features, and short stature. This deletion was identified prenatally in three cases, one case with a midline defect, one case with increased nuchal translucency, and the third case with structural brain malformation (203,205). When parental testing was performed, roughly half were found to be *de novo* and half were inherited from unaffected or variably affected parents. Variable expressivity and incomplete penetrance has been observed in each family studied.

**45.4.11.2 Cytogenetics and Molecular Cytogenetics.** The 16p13.1 deletion is recurrent, with a common size of about 1.13 Mb. Fourteen annotated genes are within the common deletion, with reduced dosage of the NDE1 and NTAN1 genes thought to be the cause of the neurocognitive phenotype seen with this deletion (81). NDE1, also known as NUDE, is expressed in the brain and the protein product interacts with Lis1, which is important for normal brain formation. NTAN1 deficiency is related to memory dysfunction and social behavior in the mouse (206).

#### 45.4.12 16p11.2 Microdeletion

The 16p11.2 deletion is a newly characterized syndrome without a consistent phenotypic pattern but with almost

complete penetrance. It is one of the most commonly detected deletions in individuals tested by CMA in the clinical setting. This deletion was first described in 2007 by two independent groups, in a report of *de novo* copy number change in a cohort of individuals with autism spectrum disorder (207) and in a set of monozygotic twins with cardiac defect, intellectual disability and seizures (208). Since the initial reports, more than 100 individuals with 16p11.2 deletion have been reported in the literature (83,209).

**45.4.12.1 Clinical Presentation.** The 16p11.2 deletion has been associated with cardiac defects, developmental delay, skeletal abnormalities, genitourinary tract anomalies, obesity, neurobehavioral abnormalities (including autism), and dysmorphic features. Despite the variability of the phenotypes, some features are more common including developmental delay, intellectual disability, and/or autism spectrum disorder, and obesity (210). Delays are observed more in language and cognition than in motor skills. Recently, some individuals with normal intellect have been reported (211). Carriers of the 16p11.2 deletion are thought to have a higher risk of seizures as compared to noncarriers; however, long-term follow-up data is not available. Most of the deletions are *de novo* with several examples of inheritance from an affected parent; however, affected parents have presented with clinical features that are different from those seen in the probands (212).

**45.4.12.2 Cytogenetics and Molecular Cytogenetics.** The 16p11.2 deletion is a recurrent deletion mediated by LCRs. The deletion is commonly about 580 kb and contains 25 annotated genes including ALDOA, DOC2A, SEZ6L2, TAOK2, HIRIP3, MAPK3, MAZ, and PPP4C. Of note, there is another recurrent 200 kb deletion on 16p11.2 distal to the one described here. This distal 200 kb deletion includes the SH2B1 gene and has been associated with developmental delay and obesity (213).

#### 45.4.13 Miller-Dieker Syndrome

Deletion of the distal end of the short arm of chromosome 17 is associated with a distinct syndrome of facial dysmorphism in combination with lissencephaly (214). Some patients with isolated lissencephaly (ILS), in the absence of other dysmorphic features, have also been found to have deletions of this region of the genome (215). The deletions in this disorder do not occur between LCRs; the breakpoints are variable and nonrecurrent.

**45.4.13.1 Clinical Presentation.** Miller-Dieker syndrome (MDS) is characterized by type I lissencephaly (smooth brain, absent gyri and smooth cortical surface) and distinctive facial features including a prominent forehead, bitemporal hollowing, midface hypoplasia, a small jaw, short nose with upturned nares, and a protuberant upper lip with thin vermilion border. At the clinical level, MDS and ILS can be differentiated by the presence of

significant dysmorphic facial features and a more severe grade of lissencephaly in MDS.

Patients also demonstrate severe postnatal growth retardation and seizures (216–218). Seizures often set in early after birth and are reported to be of various types (219). Polyhydramnios is common during pregnancy, probably because of poor fetal swallowing movements. All patients have profound intellectual disability, diminished spontaneous movements, prominent opisthotonus and limb spasticity. In one study of 26 patients, 6 had died by the age of 4 years (214).

#### 45.4.13.2 Cytogenetics and Molecular Cytogenetics.

The occurrence of several families in which there were multiple affected siblings initially suggested that MDS was a recessive condition. It has now been shown that most of the known familial cases are due to a parental balanced translocation or pericentric inversion (220,221). MDS is associated with a deletion of chromosome 17p13.3, which is visible by high-resolution cytogenetic methods in about 50% of cases (214). The size of the deletion in these patients is variable, and there is no apparent difference in clinical manifestation among patients with different size deletions, suggesting that only one or a small number of genes within 17p13.3 are responsible for the phenotype.

Microdeletions of 17p13.3 have been detected in many patients with apparently normal chromosomes and features of MDS. Using cytogenetic and molecular techniques, deletions of 17p13 are detectable in about 90% of MDS patients and in about 15% of patients with ILS (215,222). Studies comparing deletion breakpoints in patients identified a critical 350kb region for MDS, and identified *LIS1* (lissencephaly-1, also known as *PAFAH1B1*) as a critical gene in lissencephaly. Point mutations have been identified in the *LIS1* gene in patients with the ILS sequence. Deletions of 17p13.3 and the *LIS1* gene result in a phenotype that can vary from the ILS sequence to MDS. Deletion of the *CRK* and 14-3-3 epsilon (*YWHAE*) genes occurs in patients with the most severe lissencephaly grade. *YWHAE* plays a role in cortical development and may contribute to the more severe form of lissencephaly seen only in patients with MDS (223). Facial dysmorphism and other anomalies in MDS patients appear to be the consequence of deletion of genes distal to *LIS1*.

#### 45.4.14 Hereditary Neuropathy with Liability to Pressure Palsies (HNPP)

Approximately 80% of individuals with hereditary neuropathy with liability to pressure palsies (HNPP) (MIM:162500) have a recurrent deletion on 17p12, while the reciprocal duplication is associated with CMT type 1A, and this pair of disorders has been shown to occur via NAHR.

**45.4.14.1 Clinical Presentation.** HNPP is a focal compression peripheral neuropathy that is characterized by episodic numbness, tingling or weakness in response to

nerve injury from pressure. Absent ankle reflexes are seen in about half of the individuals with this condition. Neuropathy is seen of both motor and sensory nerves. The common presenting symptom is neuropathy of a single nerve without any pain (224). The peroneal nerve is the most commonly affected nerve resulting in a foot drop. The ulnar nerve, brachial plexus, and the radial nerve are also frequently seen affected. Nerve conduction delays are noted on electrophysiologic studies (225). Subclinical central nervous system lesions (in white matter) are observed occasionally (226). The nerve injury causes demyelination with gradual recovery over time, although recovery may not be complete for several months. Onset is usually seen within the first and second decades of life. In the pediatric population, the 17p11.2 deletion can be detected as an incidental finding by CMA (227). Variability in the severity is often noted and some individuals are reported to be asymptomatic. Carpal tunnel is often seen in individuals with HNPP; however, HNPP is not a cause of most cases of isolated carpal tunnel syndrome (228).

#### 45.4.14.2 Cytogenetics and Molecular Cytogenetics.

A 1.4 Mb deletion involving the *PMP22* gene is the cause of HNPP in 80% of patients, with the remainder of cases resulting from intragenic mutations of this gene. The deletion is recurrent and lies between LCRs (CMT1A-REP). The CMT1A and HNPP reciprocal duplication/deletion syndromes have been used as a model to work out the mechanisms for recurrent deletion/duplication syndromes (229).

#### 45.4.15 Smith-Magenis Syndrome

SMS was first described in 1986, and patients have a constellation of features including facial dysmorphism, short stature, cleft palate, behavioral problems and intellectual disability. The syndrome is associated with a cytogenetically detectable 3.7-Mb interstitial deletion within chromosome band 17p11.2 (230,231). The incidence of birth is estimated at 1/25,000. The deletion is recurrent, with greater than 90% of patients presenting with a common deletion.

**45.4.15.1 Clinical Presentation.** The phenotype includes brachycephaly, midfacial hypoplasia with a broad flat midface, broad nasal bridge, prognathism, hoarse voice, speech delay, cognitive delay, psychomotor and growth retardation, and behavioral problems (232). The brows are heavy with excess lateral extension of the eyebrows. The nose has a depressed root and, in the young child, a scooped nasal bridge. Hearing loss is present in ~50% of cases and hyperactivity and behavioral problems are present in most. Two-thirds of the patients demonstrate self-injurious behavior including pulling out fingernails and toenails, insertion of foreign bodies into body orifices, and head banging. Ocular abnormalities are frequent and include high myopia, retinal detachments, iris anomalies, microcornea, strabismus and cataracts (230,231,233–235).

Patients demonstrate normal nerve conduction velocities, despite the fact that signs suggestive of peripheral neuropathy are found in 75% of patients (e.g. decreased or absent deep tendon reflexes, pes planus or pes cavus, decreased sensitivity to pain, and decreased leg muscle mass) (232). Notable symptoms of sleep disturbance (difficulty falling asleep, difficulty staying asleep, and frequent awakening during the night) have been observed in a significant number of patients (235). In 57% of patients, abnormalities in rapid eye movement (REM) sleep have been demonstrated by polysomnography (232,235). Patients with SMS manifest unusual hand- or arm-clasping behavior (self-hugging), which appears to be part of a complex upper body tic, exacerbated by happiness, excitement or over stimulation (236).

#### 45.4.15.2 Cytogenetics and Molecular Cytogenetics.

In the majority of patients, the syndrome is related to a cytogenetically visible, *de novo*, interstitial deletion of a portion of 17p11.2 (230,231). One patient with complete deletion of band 17p11.2 was more severely affected with facial malformations, cleft palate, and major anomalies of the cardiac, skeletal and genitourinary systems. Parent-of-origin studies on 15 patients demonstrated 9 paternal and 6 maternal deletions. The apparent random parental origin suggested that genomic imprinting does not play a role in the expression of the SMS clinical phenotype (233).

It has been demonstrated that NAHR between copies of a repeat gene cluster (SMS-REP) that flank the deletion is responsible for this microdeletion disorder (237). Several patients with SMS with atypical interstitial deletions at 17p11.2 demonstrated deletions of the retinoic acid induced 1 (*RAI1*) gene (238). Further, point mutations in the *RAI1* gene, which lies within the SMS critical interval, have been identified in patients with many SMS features in whom no deletion was detected (239,240).

### 45.4.16 17q12 Microdeletion

The 17q12 microdeletion is a recurrent 1.5 Mb deletion that encompasses the *HNF1B* (*TCF2*) gene. The first deletions involving the *HNF1B* gene were identified in patients with MODY 5 (241), and this is the first microdeletion to be associated with diabetes.

**45.4.16.1 Clinical Presentation.** The phenotypic spectrum of this disorder includes diabetes, pancreatic abnormalities as well as autism spectrum disorder, mood disorders, intellectual disability, speech delay, seizures and structural brain malformations (87,242,243). Neurocognitive features demonstrate reduced penetrance. Mefford et al. reported a *de novo* deletion in a fetal autopsy sample with dysplastic kidneys (244). Deletions also result in kidney cysts, hypo/dysplastic kidneys, and single kidneys (245,246).

**45.4.16.2 Cytogenetics and Molecular Cytogenetics.** Deletions of 17q12 are recurrent and mediated by SD. The common size of the deletion is between 1.06 and

2 Mb. The minimum deleted region (~1 Mb) includes 13 annotated genes including *HNF1B* also known as *TCF2*, *LHX1* and *ACACA*. Mutations of *HNF1B* result in renal cysts and diabetes syndrome (MIM# 137920), features that are seen in the 17q12 deletion. *LHX1* haploinsufficiency is hypothesized to take part in the neurocognitive phenotype of the syndrome (87).

### 45.4.17 17q21.31 Microdeletion

The 17q21.31 microdeletion syndrome was one of the first syndromes identified with the use of CMA technology (12,13). The 17q21.31 microdeletion has a clinically recognizable phenotype that includes characteristic facial features, hypotonia, developmental delay, abnormal hair structure and a characteristic, friendly disposition (88,247). This is a recurrent microdeletion.

**45.4.17.1 Clinical Presentation.** To date 40 patients with this deletion have been reported (12,13,88,247–249). The common dysmorphic features of these individuals include pear-shaped nose with bulbous tip, abnormal hair structure, ptosis, blepharophimosis, long face with broad forehead, and anteverted ears. Global developmental delay is evident in early childhood; language and speech is significantly affected. The degree of cognitive impairment is variable. Hypotonia and a friendly personality are seen in ~80% of the deletion carriers. Seizures, lax joints, cryptorchidism, and structural brain abnormalities are noted in roughly half of all the reported individuals. Scoliosis/kyphosis, ocular and cardiac abnormalities are noted frequently as well.

**45.4.17.2 Cytogenetics and Molecular Cytogenetics.** The commonly deleted size of this recurrent deletion is 500–700 kb, and a 424 kb critical region within the commonly deleted region has been identified (88). Six genes (*C17orf69*, *IMP5*, *STH*, *KIAA1267*, *CRHR1*, and *MAPT*) reside within the critical region. Haploinsufficiency of *MAPT* is thought to be the cause of this syndrome. Of note, gain-of-function mutations of *MAPT* result in progressive dementias (MIM# 601104; 260540; and 600274). In all the reported patients this deletion was found to be *de novo* when parental testing was available. An inversion of chromosome band 17q21.31 is detected in all originating parental chromosomes (250). This 900 kb inversion is present in 20% of individuals with European ancestry, and may predispose carriers for the 17q21.31 deletion in offspring (251).

### 45.4.18 18p Monosomy

The 18p- syndrome was first described in 1963 (252). The incidence is estimated to be about 1:50,000 live-born infants. Deletions of 18p have variable breakpoints and this is not a recurrent disorder.

**45.4.18.1 Clinical Presentation.** The main clinical manifestations include intellectual disability, growth retardation, round face, dysplastic ears, wide mouth with

dental anomalies, and abnormalities of the limbs, genitalia, brain, eyes, and heart. The pattern of abnormalities seen in patients with deletion of 18p may not be striking at birth, but becomes more evident by 3 years of age. Newborns have mild to moderate growth retardation (mean birth weight at the 5–10 percentile). Affected neonates demonstrate brachycephaly, a broad face with ptosis of the upper lids, strabismus, hypertelorism, a broad nose, downturned corners of the mouth, micrognathia with a wide mouth and large protruding ears. Teeth are irregularly set and are particularly prone to caries (253). Holoprosencephaly is present in at least 10% of patients. Heart defects, primarily septal defects are seen in less than 10% of patients. IQs range from 25 to 75, with an average of 45–50. Speech is particularly delayed and many patients do not speak before 7 years. Prognosis is poor for patients with holoprosencephaly, but patients without this defect do not have a shortened life expectancy (254). There are at least four reports of patients with partial deletion of 18p (with breakpoints in 18p11.2 or 18p11.3) who have reproduced (255–258). Consistent features in these cases included mild intellectual disability with short stature, ocular abnormalities (cataracts, extropia, myopia), and microcephaly reported in some cases.

Multiple cases have been identified on prenatal diagnosis, following abnormalities seen on ultrasound. In one case, holoprosencephaly was identified at ultrasound, with 18p deletion confirmed on follow-up chromosomes (259). In another case, a chromosome abnormality was picked up after amniocentesis for advanced maternal age, but an ultrasound at 20 weeks revealed increased nuchal translucency as the only abnormality (260).

#### 45.4.18.2 Cytogenetics and Molecular Cytogenetics.

Most 18p- patients have a cytogenetically detectable deletion of almost the entire short arm of chromosome 18. This is not a recurrent abnormality, and is not mediated by LCRs. This deletion occurs *de novo* in about 85% of patients, with the remainder of 18p- individuals resulting from the malsegregation of familial rearrangements. There have also been a few instances of *de novo* unbalanced rearrangements involving translocation of the 18 centromere and long arm onto the short arm of an acrocentric chromosome, resulting in monosomy 18p (259,260). Some deletions have been the result of cryptic translocations involving other subtelomeric regions (261).

### 45.4.19 18q Monosomy

Partial deletion of the long arm of chromosome 18 leads to a clinically recognizable, although variable syndrome. The deletions of 18q that have been studied have highly variable breakpoints and there are good correlations between genotypes and phenotypes (262,263). These highly variable deletions are nonrecurrent and are not associated with specific genomic architecture. There are SDs within chromosome 18q, but there does not seem

to be a preference for breakpoints that are mediated by these, with a couple of exceptions (264).

**45.4.19.1 Clinical Presentation.** Clinical features of the 18q- syndrome are variable, consistent with the variable sizes of the deletions. Consistent features include hypotonia, dysmyelination of the central nervous system, decreased or absent deep tendon reflexes, short stature, and hearing impairment. Facial dysmorphism consists of midface hypoplasia, deeply set eyes, short nose, and a “carp” mouth (large, open mouth with corners slanting downward, short upper lip, absent Cupid’s bow). Ears are characteristic with prominent antitragus and anti-helix. Atresia of the external auditory canal has been identified in about 50–65% of patients, and hearing loss has been noted. Fingers are long, thin and tapered with protuberant fingertips and toes are irregularly implanted and overriding. Both sexes demonstrate abnormal genitalia, with cryptorchidism and hypospadias in males and hypoplasia of the labia minora in females. Growth hormone insufficiency is a common cause of growth failure in 18q- individuals. Neurologic findings include hypotonia, poor coordination, choreoathetotic movements and spinal muscular atrophy. Intellectual disability is generally present, but varies from mild to severe. Patients have been reported with only learning disabilities, although half the patients have an IQ between 30 and 50 (265). Life expectancy is apparently normal and many affected adults have been described. There are multiple reports of this chromosomal abnormality being transmitted from parent to child (266,267).

#### 45.4.19.2 Cytogenetics and Molecular Cytogenetics.

The breakpoint of the deletions on the long arm of chromosome 18 have been found to vary between 18q21 and 18q23 with widely ranging deletion sizes from 0.5 Mb to more than 30 Mb. The highly variable breakpoints in this syndrome do not appear to be mediated by LCRs. Several different types of cytogenetic abnormalities have been found to be associated with deletions of 18q, and of 189 patients who were studied, 130 (69%) had simple terminal deletions, 11 (6%) had deletion/duplication events, 29 (15%) had interstitial deletions, 4 (2%) had deletions resulting from a translocation, and 15 (8%) had deletions resulting from capture of another chromosome’s telomere. About 94% of the alterations were *de novo*, and 87% of *de novo* deletions occurred on the paternal chromosome (264). Critical regions have been identified for several features including dysmyelination, kidney malformations, and aural atresia; however, key genes have not been identified to date (263).

### 45.4.20 Chromosome 22q11.2 Deletion Syndrome

Deletions of the proximal long arm of chromosome 22 have been associated with several well-studied, clinically identified syndromes. They include DiGeorge Syndrome (DGS), the velocardiofacial syndrome (VCFS) (268,269)

and the conotruncal anomaly face syndrome (CAFS) (270). All three syndromes share the same molecular lesion, a deletion within band 22q11.2. Conotruncal cardiac defects are common to all three described syndromes and studies have shown that there is a subgroup of patients with conotruncal defects who demonstrate deletions of 22q that can be identified at birth (271). It is now known that the majority of patients with DGS, VCFS, and CAFS have deletions of 22q11 (269). Thus, these syndromes are presumed to be slightly different manifestations of the same disorder. The 22q11.2 deletions occur between LCRs in the 22q11.2 region and are recurrent deletions (272,273). The overall frequency of the 22q11.2 deletion syndrome (22q11.2 DS) is estimated to be approximately 1/2000–1/6000 live births (274–276).

**45.4.20.1 Clinical Presentation.** The 22q11.2 deletion syndrome is characterized by cognitive, behavioral and physical anomalies (277). Patients demonstrate extreme phenotypic variability, and intrafamilial variability is common. Conotruncal cardiac malformations occur with an increased frequency in patients. Interrupted aortic arch type B (IAA), truncus arteriosus (TA), and tetralogy of Fallot (TOF) are the predominant cardiac lesions observed in DGS patients while TOF and ventricular septal defects (VSDs) are common in VCFS. Goldmuntz and colleagues (271) showed that 20–30% of newborns and infants with apparently nonsyndromic conotruncal cardiac defects have microdeletions of 22q11. Deletions of 22q11 have been described in cases of familial CHD as well (see Chapter 46). Careful examination of these individuals has identified subtle dysmorphic facial features or learning disabilities that are more suggestive of the diagnosis of DGS/VCFS; however, some of these features may not be apparent until a child reaches school age.

DGS was originally characterized by the absence or hypoplasia of the thymus and the parathyroid glands, cardiac malformations and dysmorphic facial features (278). Affected organs are derived from the embryonic third and fourth pharyngeal pouches and the syndrome is presumably a developmental defect of these structures. Absence or hypoplasia of the parathyroid glands may lead to hypocalcemia that presents as neonatal tetany or seizures. Hypoplasia of the thymus causes susceptibility to infection because of a functional deficit of T cells. The cardiac malformations include TOF, IAA, TA, conoventricular septal defect, right-sided aortic arch and aberrant right subclavian artery. Craniofacial dysmorphism can include micrognathia, cleft palate, bifid uvula, low-set ears and hypertelorism with short palpebral fissures. Defects in other organ systems have been reported (278–280). VCFS was initially characterized in patients with cleft palate, cardiac defects, speech and learning disabilities and a typical facial appearance (281–283). CAFS has been characterized by the presence of conotruncal cardiac defects in association with a characteristic facial appearance. The facial features include ocular hypertelorism,

lateral displacement of the inner canthi, flat nasal bridge, small mouth, narrow palpebral fissures, bloated eyelids, and malformed ears.

Since the disorder and the microdeletion segregate in an autosomal dominant mode, one should pay particular attention to the presence of minor features such as facial dysmorphism and mild cognitive impairment in the parents of deletion-positive probands. Parents of deletion-positive children should be examined by a clinical geneticist and tested to ascertain their carrier status with regard to a 22q11 deletion. Individuals with a 22q11 deletion have a 50% risk of transmitting the deletion-bearing chromosome to his or her offspring. Antenatal detection of the deletion has been successfully performed on cultured amniocytes and chorionic villi obtained from at-risk pregnancies. However, as there is a wide range of phenotypic features seen in association with the 22q11 deletion, one cannot predict the phenotypic outcome based on the results of molecular cytogenetic studies.

**45.4.20.2 Cytogenetics and Molecular Cytogenetics.** Approximately 15–20% of patients with DGS have abnormalities on karyotype (280). The majority of these cytogenetically abnormal cases involve chromosome 22. These are either unbalanced translocations with monosomy 22pter-->q11 (280,284–288) or interstitial deletions, del(22)(q11.21q11.23) (268,280,289–291). Even with high-resolution banding techniques, translocation-mediated or interstitial deletions are observed only in less than 25% of cases. Using molecular techniques (FISH, multiplex ligation-dependent probe amplification (MLPA), quantitative PCR (qPCR) or CMA), deletions of 22q11 can be demonstrated in the majority of patients diagnosed with either DGS or VCFS (268,291,292). Mutations of TBX1, located within the chromosome band 22q11.21, have been identified in several patients without the 22q11.2 deletion (293,294). These results suggest that the TBX1 gene is a major genetic determinant of the features of the 22q11.2 deletion syndrome.

Although the majority of cases of DGS are now attributable to a 22q11 deletion, other chromosome defects have been seen in association with DGS, including 10p13 monosomy, and deletion of 18q21.33 (280,295). In addition, there is evidence that teratogens and maternal diabetes are potential causes of the DGS phenotype, especially in individuals without a 22q11 deletion. The diagnostic management of a patient with DGS should include a molecular test to determine whether there is a 22q11.2 deletion. In the case of a deletion-positive proband, parents should be screened to determine their carrier status.

#### 45.4.21 22q13 Subtelomere Deletion (Phelan-McDermid Syndrome)

The Phelan-McDermid syndrome results from the loss of 22q13 by simple deletion, unbalanced translocation, ring

chromosome formation, or other unbalanced structural change. It is not mediated by LCRs.

**45.4.21.1 Clinical Presentation.** Numerous patients with deletions of 22q13 have now been reported in the literature (296–298). The clinical phenotype is characterized by hypotonia, developmental delay, severe language delay, and mild facial dysmorphism (epicanthal folds, large dysplastic ears, supraorbital fullness, upturned/blunted nasal tip and smooth philtrum). Features seen in a subset of patients include dolichocephaly, two to three toe syndactyly, joint hyperextensibility, seizures and abnormal nails. Most patients demonstrate normal to advanced growth parameters. In a study of 37 individuals with deletions of 22q13 ascertained through a 22q13 family support group, the age range was from 12 months to 26 years, and the number of males and females was similar (17 males, 20 females) (296). There have also been reports of individuals with deletion of 22q13 on one chromosome 22 homolog in whom a recessive allele in the *ARSA* gene (located at 22q13) was unmasked, resulting in metachromatic leukodystrophy (299). This should be considered particularly in patients with metachromatic leukodystrophy who manifest more severe neurologic involvement.

**45.4.21.2 Cytogenetics and Molecular Cytogenetics.** Deletions involving 22q13 have been detected both cytogenetically (deletions, ring chromosomes) and by FISH in individuals with an apparently normal karyotype. In some cases, these deletions have been identified after referral to rule out DGS/VCFS, and FISH using the DiGeorge/VCF probe set revealed incidental deletion of the control probe that maps within the *ARSA* (arylsulfatase A) gene (300). Chromosome 22q13 deletions have also been identified after subtelomere analysis (162,301).

Abnormalities of 22q13 can be pure deletions, or unbalanced rearrangements with involvement of another chromosome. In the study reported by Phelan et al. (296) there were 29 terminal deletions and 8 unbalanced translocations. There was one patient identified with an apparently reciprocal translocation, 46,XY,t(12;22)(q24.1;q13.3), who demonstrated features consistent with those seen in the 22q13.3 deletion syndrome (302). Clinical features in this patient included developmental delay, severely compromised expressive language, mild intellectual disability (IQ 54), hypotonia and minor dysmorphic features (dolichocephaly, epicanthal folds, and saddle nose with bulbous tip). Molecular analysis of this translocation revealed that it bisected the proline-rich synapse-associated protein 2 (*ProSAP2*) gene. *ProSAP2*, also known as *SHANK3*, encodes a scaffold protein that is involved in the postsynaptic density of excitatory synapses, and is preferentially expressed in the cerebral cortex and cerebellum. Haploinsufficiency of this gene is the cause of the major neurological features associated with deletion 22q13 (303,304).

## 45.5 DUPLICATION

### 45.5.1 Supernumerary Chromosomes

Small supernumerary chromosomes are seen in approximately 0.06% of the population (305). These small chromosomes are sometimes referred to as “marker” chromosomes. Marker chromosomes are defined as abnormal chromosomes that cannot be fully characterized based on standard cytogenetic analyses because of their paucity of banding landmarks. FISH and CMA analyses have shown that these markers are heterogeneous with respect to size and composition and some are associated with intellectual disability and other abnormalities, while others seem to have no recognizable phenotypic effects.

Correlation between the phenotype and the chromosomal origin may permit a distinction between those markers that carry a high risk for phenotypic abnormality and those markers with a low risk. The risk for phenotypic abnormality is correlated with whether the marker is *de novo* or familial (with the risk being higher for *de novo* markers), and with the chromosomal origin of the marker. In some cases, the marker chromosomes are large enough and have some banding characteristics, which allow the cytogeneticist to make educated guesses about their origin. Other markers are very small and have no cytogenetic landmarks. In a study of 50 marker chromosomes, Blennow et al. identified 37 markers that were of acrocentric origin (25 from chromosome 15), 5 isochromosomes for 18p, one isochromosome for 12p (Pallister Killian), and one each derived from chromosomes 4, 7, 8, 9, 19, and 20. In this section, we describe five syndromes associated with relatively well-studied supernumerary chromosomes.

### 45.5.2 Pallister-Killian Syndrome

The Pallister-Killian syndrome is a relatively rare disorder characterized by multiple dysmorphic features and severe intellectual disability and tissue-specific mosaicism. The cytogenetic abnormality is not generally observed in peripheral blood lymphocytes analyzed by G-banding and therefore the diagnosis could be missed if the proper diagnostic test is not carried out.

**45.5.2.1 Clinical Presentation.** Patients with Pallister-Killian syndrome have a very coarse face with pigmentary skin anomalies, localized alopecia, profound intellectual disability and seizures. In infancy the hair is sparse, particularly in the frontal area. Patients have a prominent, high forehead, hypertelorism, epicanthal folds, flat nasal bridge, large mouth with downturned corners and abnormal ears. The neck is often short and webbed, with excess nuchal skin. There is a relatively high incidence of diaphragmatic defects and supernumerary nipples. Affected newborns are profoundly hypotonic. Adults with the disorder demonstrate severe intellectual disability, epilepsy,

coarse facies and macroglossia (306–309). There have been a few exceptional patients who have been reported to have a mild phenotype, including mild intellectual disability (310).

The consistently mosaic nature of this chromosome abnormality can make prenatal diagnosis difficult. Prenatal findings on ultrasound that indicate a risk of the Pallister-Killian syndrome include broad neck, short limbs, abnormal hands or feet, diaphragmatic hernia and hydramnios. The diagnosis has been made after an abnormal screen for nuchal translucency (311).

#### 45.5.2.2 Cytogenetics and Molecular Cytogenetics.

Historically, in most Pallister-Killian patients studied by cytogenetic (G-banding) analysis, lymphocyte chromosomes are found to be normal but fibroblasts show an extra, small metacentric chromosome. The supernumerary chromosome has been demonstrated to be an isochromosome for the short arm of chromosome 12 (i(12p)) (312). The i(12p) has been demonstrated in a high percentage of cells on direct bone marrow analysis and in a lower, but significant percentage of cells from cultured bone marrow, and it has been seen in fibroblasts from skin, lung, and testes. Recent work demonstrates that the isochromosome can be detected by CMA of DNA purified from peripheral blood. It has been hypothesized that failure to detect the isochromosome by standard cytogenetics is a result of selection against it in the cells that respond to phytohemagglutinin (PHA) stimulation. When culturing is not carried out the isochromosome may be detected, either by microarray or by interphase FISH (313). Nevertheless, it is still important to consider the possibility of tissue-limited mosaicism when a negative result is obtained in one tissue (314,315). The percentage of cells containing the supernumerary i(12p) has varied widely among patients studied. The frequency of the i(12p) has been found to be higher in amniotic fluid than in chorionic villi or cord blood. The percentage of fibroblasts containing the marker has been observed to decrease over time (316–318). The marker can be inherited from either parent, although of six cases reported, it was maternal in five (319).

### 45.5.3 Isodicentric 15 Syndrome (Tetrasomy 15q)

The isodicentric 15 syndrome (tetrasomy 15q) accounts for approximately 40% of marker chromosomes, with an incidence of about 1/30,000. The rearrangement is mediated by the genomic architecture within 15q11q13, which is highly repetitive as described for Prader-Willi and Angelman syndromes. The marker associated with the tetrasomy 15q syndrome is genetically distinct from smaller, benign marker chromosomes derived from chromosome 15. Markers that do not extend into the Prader-Willi/Angelman syndrome critical region are often benign and may be familial, while markers that include this region are pathogenic (320–324). Thus, the clinical

presentation is dependent on the size of the marker, with smaller markers found in normal individuals (325,326), while the larger markers are associated with the tetrasomy 15q syndrome.

**45.5.3.1 Clinical Presentation.** Patients with tetrasomy 15q syndrome present with clinical abnormalities including central hypotonia, developmental delay, intellectual disability, epilepsy and autistic behavior (327,328). Patients with tetrasomy 15q can present during the first year with hypotonia and acquisition of milestones is delayed. Expressive language is particularly poor with echolalia. Affected children are often categorized as autistic (321,322,329–331). Many reported cases of tetrasomy 15q have been identified in patients studied because of intellectual disability. These patients are generally nondysmorphic, although facial features have been described as coarse and various minor dysmorphic features have been described, including flattened nasal bridge and anteverted nares (330). Affected individuals demonstrate developmental delay from an early age and other associated features include psychomotor retardation, seizures, hyperactivity and behavioral disturbances, including violent behavior (328,329,332,333). There have been a few cases of hyperpigmentation, which may be associated with duplication of the P gene, which is located within 15q11q13, and is known to be involved in pigmentation (334). Lifespan does not appear to be reduced, although there have been a few reports of progressive loss of function (335).

#### 45.5.3.2 Cytogenetics and Molecular Cytogenetics.

Isodicentric chromosomes consist of two copies of the p arm (satellites), centromere, and proximal long arm of chromosome 15, which are fused at the proximal long arm. The presence of SDs in this region is consistent with the high frequency of this marker chromosome. These regions are known to contain a large number of LCR sequences, and it has been proposed that illegitimate recombination between these repeats may be involved as a mechanism in the formation of structural anomalies involving 15q11q13 (336). Historically, this chromosome marker was described as an inverted duplication 15 (inv dup(15)); however, the nomenclature has been updated to reflect the origin of the marker, which is known to arise from both chromosome 15 homologs (dic(15;15)). While it may be difficult to differentiate the benign smaller dic(15;15) markers from the larger pathogenic ones by cytogenetics alone, the determination of genetic composition of the dic(15;15) is now straightforward with the use of array-based techniques. Pathogenic dic(15;15) markers include the Prader-Willi/Angelman syndrome critical region (337).

### 45.5.4 Isochromosome 18p (Tetrasomy 18p Syndrome)

The isochromosome 18p occurs as a supernumerary marker chromosome, with two copies of the short arm

of chromosome 18, resulting in tetrasomy 18p. This isochromosome is presumably compatible with life, because chromosome 18p is relatively gene poor.

**45.5.4.1 Clinical Presentation.** Patients with i(18p) demonstrate a recognizable phenotype characterized by low birth weight, microcephaly, hypotonia, camptodactyly or adducted thumbs and a typical facial appearance. There is hypotonia and feeding difficulties in the first year and spasticity develops by the second year. Intellectual disability in the moderate to severe range is present in all individuals studied. Some patients (about 50%) suffer from seizures. Facial dysmorphism includes dolichocephaly, a round face with small, low-set ears, short palpebral fissures and small mouth, although with increasing age, prognathism develops and the mouth and nose become more normal in size (338–340). Skeletal abnormalities including scoliosis, kyphosis, hypoplasia of the iliac wings, long narrow fingers and toes and rib abnormalities are prevalent. Orthopedic problems are a common issue among adult patients.

**45.5.4.2 Cytogenetics and Molecular Cytogenetics.** The marker chromosome is a small, metacentric marker, which can usually be identified as an i(18p) on the basis of its size and banding pattern. Callen et al. (340) studied nine patients with marker chromosomes thought to be an i(18p) based on banding and confirmed their origin from chromosome 18 using a chromosome 18 alpha satellite probe in combination with a probe mapping to 18p11.3. This marker chromosome usually occurs *de novo*; however, a few familial cases have been reported (341–343). In most, but not all, cases studied, the marker was maternally derived (344,345).

## 45.5.5 Cat Eye Syndrome

The name for this syndrome is derived from the “cat-eye-like” appearance of the pupil, which results from coloboma of the iris, one of the features of the syndrome. There is a high variability of clinical features noted. Cat eye syndrome (CES; MIM# 115470) is most often associated with a supernumerary, bisatellited, dicentric marker, although some patients with interstitial duplications of the 22q11.2 region have also been identified (346–348). The marker chromosome and interstitial duplications are mediated by LCRs within chromosome 22q and there is overlap between the genes that are involved in CES and the der(22) syndrome (Emanuel syndrome) (349). This is a recurrent disorder, and the marker often appears in mosaic form, presumably due to somatic loss.

**45.5.5.1 Clinical Presentation.** CES demonstrates significant variable expressivity (350). In addition to the characteristic ocular anomaly, other clinical features of CES include renal malformations, urinary tract anomalies, congenital heart defects, anal atresia with fistula, imperforate anus, preauricular tags or fistulas, heart malformations, and mild to moderate intellectual disability

Some patients have normal intelligence, but display psychiatric symptoms. Inferior iris coloboma occurs in less than half the cases. Preauricular skin tags and/or pits constitute the most consistent feature. There have been numerous examples of transmission of the marker from parent to child with variability in the phenotype (351,352).

**45.5.5.2 Cytogenetics and Molecular Cytogenetics.** The characteristic chromosomal change is the presence of an additional acrocentric marker chromosome, usually bisatellited, derived from chromosome 22. The marker chromosomes are variable in size and can be asymmetric with regard to the region duplicated (352). Three sizes of supernumerary CES chromosomes have been identified but the phenotype associated with the larger duplicated chromosome is no more severe than that of the smaller cat eye chromosome, and sizing of the duplicated segment has little prognostic value (353). A 2–2.5 Mb critical region contains 14 genes, with CECR1 (cat eye critical region 1) and CECR2 as possible candidates based on function and expression pattern (349). In addition to a supernumerary marker, there has been a case of CES exhibiting all the major symptoms including coloboma, preauricular anomalies, heart defect, kidney malformation, and anal atresia caused by interstitial duplication of the CES critical region on 22q11.2, resulting in partial trisomy 22q11.2 (348).

## 45.5.6 Supernumerary der(22)t(11;22) Syndrome (Emanuel Syndrome)

**45.5.6.1 Clinical Presentation.** Patients with the +der(22) t(11;22) syndrome (Emanuel syndrome) have a distinctive phenotype, which consists of severe intellectual disability, preauricular tag or sinus, ear anomaly, cleft or high-arched palate, micrognathia, heart defects (354) and genital abnormalities in the male. The cytogenetic findings associated with this syndrome have been discussed previously in this chapter (see Recurrent Translocations).

## 45.5.7 Recurrent Microduplications

These duplications are mediated by LCRs, and are reciprocal to the deletions of these regions that have been described earlier. The critical regions and mechanisms were covered in the earlier section on deletions.

**45.5.7.1 7q11.23 Microduplication.** The 7q11.23 microduplication is a recurrent duplication, and involves the same critical region that is deleted in patients with Williams syndrome. The duplication was identified fortuitously, when a sequence from within the duplication was used as a control in a real-time qPCR test to detect 22q11 deletions (355). The associated phenotype has a consistent clinical presentation. The duplicated genetic material is generally found in a tandem orientation (355).

The most consistent clinical feature seen in patients with the 7q11.23 duplication is speech delay, which is seen in all patients. Developmental delay is seen in close to 90% of patients, with a wide range in severity. Normal intelligence has been reported in about 10% of cases. Other features include hypotonia (70% of cases), epilepsy (20%), nonspecific magnetic resonance imaging (MRI) abnormalities (70%), autism (40%), congenital heart defects (<20%) and joint laxity (>20%). Age at diagnosis varies from the first year of life if hypotonia or seizures are present up to ages of 10 or 11 (355,356). The duplication is inherited in about 60% of cases and parents with the duplication are often found to have some consistent features ranging from intellectual disability to a history of expressive speech delay. There are characteristic facial features among the affected individuals, which can be subtle (356).

**45.5.7.2 8p23.1 Microduplication.** In the late 1990s several individuals were identified with cytogenetically visible duplication of 8p23.1 that was described as clinically inconsequential (357,358). Subsequently, 8p23.1 duplications were also associated with heart defects and Coffin Lowry syndrome-like features (359). These cytogenetically indistinguishable duplications have been characterized as two separate entities with the use of molecular cytogenetic techniques. The duplications associated with normal phenotypes were found to be copy number polymorphisms of the *defensin* gene clusters, while the clinically significant duplications were found to be the reciprocal duplication of the critical region of the 8p23.1 microdeletion syndrome. The recurrent 8p23.1 microduplication syndrome is characterized by variable features of developmental delay, heart defect, and mild dysmorphic features (360,361). These duplications are sometimes *de novo*, and sometimes they are inherited from an affected parent (362). These duplications manifest variable expressivity, but all carriers of the duplication have been found to present with some associated phenotypes.

**45.5.7.3 16p11.2 Microduplication.** The 16p11.2 microduplication has been associated with variable phenotypes including developmental delay, especially in motor skills (as opposed to the severe language delays seen in the reciprocal deletion), autism spectrum disorder, dysmorphic features, and microcephaly (83,363). The duplication occurs *de novo* as well as inherited from affected parents. Similar to the 16p11.2 deletion, these duplications are characterized by variable expressivity but complete penetrance.

**45.5.7.4 Charcot-Marie-Tooth Disease Type 1A (CMT1A).** CMT disease type 1A (MIM# 118220) is a peripheral neuropathy associated with a 1.4Mb recurrent duplication within 17p12 that includes the dosage-sensitive *PMP22* gene (364). The involved region is the reciprocal of the region that is deleted in patients with HNPP, discussed previously. CMT syndrome is a demyelinating peripheral neuropathy that is characterized by

progressive weakness of the peripheral muscles. Symptom onset may occur between 5 and 25 years of age, with the most common onset in mid-adolescence or early adulthood. Muscles in the lower legs are usually the most affected, but affected individuals rarely require a wheelchair. Sensory deficits such as decreased sensitivity to heat, cold or touch may also occur. CMT is genetically heterogeneous, with multiple loci.

**45.5.7.5 Potocki-Lupski (17p11.2 duplication) Syndrome.** PTLs was first described in 2000, when targeted analysis for duplication of the repeat rich 17p11.2 region was undertaken (365). This duplication is reciprocal to the region deleted in SMS. PTLs is characterized by hypotonia and failure to thrive in infancy and early childhood, which is hypothesized to result from oropharyngeal dysphagia and hypotonia. Other features include developmental delay, intellectual disability including a severe communication disorder, and features of autistic spectrum disorder (365–367). There are characteristic sleep disturbances that include sleep-disordered breathing that can be diagnosed on sleep studies, although parents have not reported obvious sleep pattern difficulties (366). Electroencephalography (EEG) abnormalities can be detected, although patients do not experience overt seizures. More than half the patients have cardiovascular anomalies including secundum-type atrial septal defect, bicommissural aortic valve and patent foramen ovale, and mild dilated pulmonary annulus. Hypermetropia is also seen (366). While the failure to thrive is evident during the first year, this disorder has more often been diagnosed after 2 years of age in children who present with developmental delay, intellectual disability or autistic-like features (367).

While some individuals with clinical features of PTLs have been found to have duplications that are larger than the 3.7Mb common duplication, no specific additional clinical features have been delineated in these patients (368). The duplication can be difficult to identify cytogenetically, but is readily identified by chromosomal microarray studies. In a 2007 study, 35 subjects with dup(17)(p11.2p11.2) were studied, and 22 had the common, repeat flanked duplication, while the remaining 13 had duplications ranging in size from 1.3 to 15.2Mb. The common duplication occurs on both maternal and paternal chromosomes, and the precipitating crossing over event can occur via both interchromosomal and intrachromosomal mechanisms (366). In addition to the common recurrent duplication, there is another set of LCRs, and an uncommon, NAHR-mediated duplication of 5 Mb has been detected in two PTLs patients (368). Molecular analysis of a total of 74 subjects with PTLs revealed a shortest region of overlap of all the duplications (recurrent and nonrecurrent) of 125kb, which only has one gene, *RAI1*, the critical region gene for SMS.

**45.5.7.6 22q11.2 Microduplication.** The 22q11.2 microduplication is reciprocal to the 22q11.2 deletion syndromes. These duplications were identified by FISH in individuals suspected to have DGS/VCFs

(272,369). It is the most frequently identified microduplication in individuals tested clinically. Phenotypes associated with this duplication are highly variable and may be clinically unrecognizable. The phenotypic spectrum ranges from developmental delay/intellectual disability, hypotonia, hearing loss, growth retardation, and cardiac defects to a completely normal phenotype. This syndrome shares some features of its reciprocal deletion including heart defect, cleft palate, and genitourinary abnormalities; however, the phenotypes associated with the duplications are usually milder than those of the deletions (90,370,371). Although some of the duplications occur *de novo*, most are inherited from a normal or mildly affected parent. Variable expressivity and incomplete penetrance make interpretation of the clinical significance of this duplication challenging.

### Biographies

**Nancy B Spinner, PhD**, is the Evelyn Willing Bromley Professor of Pediatric Pathology and Director of the Clinical Cytogenomics Laboratory at The Children's Hospital of Philadelphia, and a Professor of Pathology and Laboratory Medicine at the Perelman School of Medicine at The University of Pennsylvania School of Medicine. She received her PhD training at The University of California at Berkeley, and her Fellowship Training in Cytogenetics at The Children's Hospital of Philadelphia. Her research interests are in the identification of the genetic etiology of pediatric disease, and her laboratory has made contributions to understanding the genetics of Alagille syndrome, Biliary Atresia and the Ring Chromosome 20 syndrome in particular. She serves on the Scientific Advisory Board of the Alagille Syndrome Alliance, and is on the Editorial Board of Human Mutation and PLoS Genetics. She has received multiple teaching awards at The University of Pennsylvania, and a Faculty Mentoring Award from the Children's Hospital of Philadelphia.

**Laura K Conlin, PhD**, is the Assistant Director of the Clinical Cytogenomics Laboratory at The Children's Hospital of Philadelphia since 2010. Laura completed her PhD training at the University of Pennsylvania in 2008, and completed her Fellowship training in Cytogenetics and Molecular Biology at The Children's Hospital of Philadelphia. Her research interests are focused on understanding the contribution of mosaicism to human genomic disease, and she is working on several disorders including Pallister-Killian syndrome, Ring Chromosome 20, as well as developing models for analysis of complex conditions such as chimerism.

**Surabhi Mulchandani, MS**, is a Genetic Counselor in the Dept of Pathology at The Children's Hospital of Philadelphia. Surabhi Mulchandani is a genetic counselor in the Cytogenomics lab at the Children's Hospital of Philadelphia. She received a Masters degree in Molecular and Human Genetics from Benaras Hindu University, Varanasi, India, and a Masters degree in genetic counseling from California State University, Northridge. Surabhi interprets the complex data generated by genome-wide array technology in context of patient's clinical information, provides genetic education, and serves as a bridge between clinicians and the laboratory. She has developed genetic education tools for the patients and providers. She plans to expand genetic education and counseling to a diverse cross-section of people.

**Beverly S Emanuel, PhD**, holds the Charles E.H. Upham Professor of Pediatrics at the Perelman School of Medicine of the University of Pennsylvania and is the Division Chief of Human Genetics at The Children's Hospital of Philadelphia. Dr Emanuel is a human geneticist investigating several diseases caused by abnormalities of human chromosomes, particularly chromosome 22. Her laboratory developed the standard diagnostic test, used by laboratories worldwide, to assess the presence of a 22q11.21 deletion and the likelihood of recurrence of deletion-based DGS/VCFS. She also investigated the duplication of genes on this chromosome that give rise to other chromosomal disorders such as supernumerary der(22) syndrome. Dr Emanuel serves on multiple editorial boards and has received several awards including the Benjamin Franklin Founders Award and the Herbert and Esther Bennet Brandwein Award in Genetic Research at The University of Connecticut.

This article is a revision of the previous edition article by John Burn and Judith Goodship, volume 2, pp 1083–1159, © 2007, Elsevier Ltd.

### 46.1 INTRODUCTION

Congenital heart defects are both common and serious. With an estimated prevalence of approximately 8 in 1000, they are the most common birth defect worldwide, and they are the most common cause of birth defect-related death (1). As a result of advances in echocardiography, fetal echocardiography, cardiac catheterization, electrophysiology, and cardiovascular surgery, many individuals with even the most severe heart lesions now survive to adulthood and lead productive lives (2). This has raised awareness of the need to identify genes involved in all forms of congenital heart disease, isolated as well as syndromic, as patients and their families ask for information regarding their risks of having a child with a congenital heart defect (3).

Although the majority of heart defects are isolated, about one-third occurs as one component of a genetic syndrome (4). Often, it is the congenital heart lesion, the presenting finding, which alerts the healthcare team to the possibility of a genetic syndrome. As with any patient with a birth defect, a primary role of the medical geneticist is to assess whether the finding is an isolated finding, or represents one manifestation of an underlying syndrome. A syndrome is typically suspected when the heart lesion is associated with findings identified on the medical, prenatal or family history, or specific dysmorphic findings (major and minor anomalies) on physical examination. In these cases, confirmatory testing may be ordered, be it chromosome analysis, fluorescence in situ hybridization (FISH), or single-gene analysis. For other cases with additional findings that are not in a recognizable pattern, array comparative genome hybridization (aCGH) is a useful comprehensive screen in the evaluation of the patient with a congenital heart defect.

Making an accurate genetic diagnosis for a patient with a congenital heart defect has several clear benefits

including the ability to provide accurate counseling on prognosis, precise causality, and recurrence risk for both the parents and the child (5). Although the same benefits exist for an isolated heart lesion, unfortunately there is simply less information. For example, counseling a couple, who have just had a child with an isolated congenital heart defect, about the risk of having another affected child remains largely unchanged by molecular analyses, and is based on empiric recurrence data (3).

Despite advances in basic science and technology, our understanding of the genetic basis of congenital heart defects remains limited. That is because congenital heart defects are not variable manifestations of a single developmental aberration. Rather, they are an etiologically heterogeneous collection of malformations, with overlapping genetic and environmental factors. Further, hindering genetic discovery is the fact that it is rare for isolated heart defects to show Mendelian inheritance, so most of the progress in this area has utilized animal models (6). However, advances in understanding the underlying genetic etiology highlight the importance of follow-up of undiagnosed patients.

This chapter provides an overview of congenital heart defects from a perspective most relevant to the clinical geneticist. Cardiac embryology is reviewed and correlated with specific cardiac lesions. We review the common genetic syndromes that have a cardiac defect as a major manifestation, categorized by etiology: chromosomal/aneuploidy syndromes, segmental chromosomal deletion/duplication syndromes, single-gene mutations, and teratogenic. Lastly, recurrence risk counseling is reviewed.

### 46.2 THE EVALUATION OF THE PATIENT WITH CONGENITAL HEART DEFECT

For the physician caring for the patient with a congenital heart defect, an important first step is to determine

whether there is an underlying syndrome or whether the congenital heart defect occurred as an isolated birth defect. Appropriate identification of a syndrome, if present, can direct the team to investigate for other organ system involvement, provide the team with important prognostic information, particularly with regard to natural history, as well as providing reproductive risk counseling for the patient or family (7). This first step can be challenging as patients can present anytime from prenatal referrals based on abnormal imaging, to the adult patient seeking recurrence risk information. Although some genetic syndromes can be readily recognized through history and physical examination, other syndromes often have variable manifestations and phenotypes that can be less apparent at birth or become less obvious with age. Therefore, the diagnostic evaluation must be approached with this continuum in mind.

The patient's medical history can be rich with diagnostic clues and it is from this foundation that the differential diagnosis can be established to guide testing strategies. Regardless of age, a careful review of the patient's medical history, prenatal history, family history, previous evaluations if obtained, can often provide the first clues in determining whether the heart defect is syndromic or isolated.

The physical examination of the patient should seek out patterns of major and minor anomalies. The best clues to an underlying diagnosis are not always the most obvious anomalies nor those with the most important impact on a patient's health, but the rarest or most atypical (8).

After review of the history, and performing a physical examination, additional investigations may be necessary to identify other anomalies. Additional evaluations can include, but are not limited to, head ultrasound or brain magnetic resonance imaging, renal ultrasound, hearing evaluation, dilated eye examination, or skeletal imaging. Identification of additional anomalies can be applied to the differential diagnosis and further refine the genetic testing strategy. In those with obvious patterns of malformations suggestive of aneuploidy, such as Trisomy 21 or Turner syndrome, a standard chromosome analysis or cytogenomic array should be obtained. Those individuals with recognized microdeletion syndromes that could be missed from standard chromosome analysis might benefit from FISH of the region of interest. Lastly, individuals presenting with patterns of malformation due to single-gene disorders would need analysis of the particular gene(s) in question. For those cases with multiple anomalies but without a recognizable syndrome, cytogenomic array analysis (aCGH) should be performed as a first-line screening test.

After a thorough clinical evaluation, it may be determined that a particular heart defect is isolated. Although the genetics of some isolated heart defects are known (see Table 46-2), genetic testing for a particular gene may not be clinically available for confirmation, or the underlying

genetic etiology remains unknown. For the infant, this may be the result of an unrecognized syndrome whose manifestations have not been fully expressed at such a young age. For older individuals, syndromes with clinical variability should be considered before concluding that a specific cardiac defect is isolated.

In the event where a specific genetic diagnosis is not made, follow-up of the patient should be arranged. Our knowledge and understanding of the genetics underlying birth defects is advancing at a rapid pace with new and affordable molecular technologies to accurately identify the underlying genetic abnormalities. Re-evaluation of undiagnosed patients is an important part of the evaluation strategy. This is particularly relevant for the adult patient who may not have had access to new testing technologies.

### 46.2.2 Embryology

A discussion of embryology is important to the understanding of isolated and syndromic congenital heart defects. The cardiovascular system is the first major system to function in the embryo as a result of the nutritional and oxygen demands of the growing embryo, which cannot be sustained by diffusion alone. Two distinct heart fields that share a common origin appear to contribute to the developing heart identified as the first and second heart fields (9). By week 3 in the humans, cells from the first heart field coalesce along the ventral midline to form the primitive heart tube. As the heart tube develops, cells from the second heart field migrate in and, with rightward looping of the heart tube, populate much of the outflow tract, future right ventricle, and atria (10). Precursors of the left ventricle are largely derived from the first heart field. Both first and second heart fields are regulated by bone morphogenic proteins, fibroblast growth factors, and Wnt and Notch proteins, from signals that arise from the adjacent endoderm (6). Once formed, the primitive heart tube must break the pre-existing L–R symmetry and undergo a series of septation events that culminates in the formation of a four-chambered heart.

L–R symmetry is first broken at 3 weeks with the rightward looping of the heart tube that occurs due to the rapid growth of the bulbus cordis and the outer curvature of the right ventricle. The mechanisms of this looping are largely unknown in humans (Figure 46-1a–e). More than 40 genes have been associated with L–R patterning in mammals and there are approximately 10 genes currently implicated in humans (11) (see Table 46-1).

During the fourth week, endocardial cushions form to begin the partitioning of the atrioventricular canal. The endocardial cushions form from the cardiac jelly, fuse with the developing atrial septum and muscular interventricular septum, remodel, and form the atrioventricular valves and septa. Transforming growth factor B, bone morphogenic proteins (BMP2A and BMP4),

FIGURE 46-1

and *ChALK2* have been implicated in this process (12). *PitX2*, *GATA4*, and *FOG-2* through its interaction with *GATA4* are also involved in the formation of the atrioventricular septum (13).

Atrial septation occurs through the growth of two septa; the septum primum that grows from the ventral and posterior walls of the atrium, and the septum secundum. As the atria enlarge, the septum primum grows toward the developing atrioventricular canal, later divided by the superior and inferior endocardial cushions. Eventually, the septum primum fuses with the atrioventricular cushions narrowing the opening between the two atria, which is then defined as the ostium primum. The septum secundum grows adjacent to the septum primum as a thick muscular fold. The septum secundum partly overlaps the septum primum and the flap-like opening is the foreamen ovale (14) (Figure 46-2 E1–H1 only). In the mouse, *Nkx2.5* is required for normal chamber formation. In humans, mutations in *NKX2-5* are associated with septal and conduction defects (15). *TBX5*, the gene implicated in Holt–Oram syndrome, is also essential for normal atrial formation and may modulate *NKX2-5* transcriptional activity (16). Additional genes implicated in abnormal atrial septal formation are listed in Table 46-2.

The atria develop on the left and right sides of the heart and are thus truly lateralized structures. The two ventricles, on the other hand, develop from the single ventricle and bulbus cordis. Ventricular septation begins at the floor of the primitive ventricle through the proliferation of the interventricular septum. A foramen exists until the end of week 7 with the formation of the membranous part of the interventricular septum with tissue contributed from the right and left bulbar ridges, and the

endocardial cushion (17) (Figure 46-3A–E). This septum eventually fuses with the aorticpulmonary septum resulting in the alignment and communication of the right ventricle with the pulmonary trunk and the aorta with the left ventricle. Failure of this process results in the common and relatively minor membranous ventricular septal defect (VSD). Although VSDs are the most common congenital heart lesion, familial clustering has been described only in rare instances and single-gene disorders have yet to be identified. Additional genes implicated in septal defects are listed in Table 46-2.

Most of the wall between the ventricles comprises the myocardium, which becomes part of the pump chamber. Much of the surface is trabeculated, giving it a web-like appearance. The right ventricle is distinguished from the left by the coarser structure of the trabecule. The programmed cell death involved in this process is a likely factor in the appearance of holes through the wall, allowing blood to cross from left to right after birth. These muscular VSDs often close spontaneously as hypertrophy of the surrounding muscle obstructs the flow. Membranous VSDs are sometimes closed secondarily by valve tissue from the tricuspid valve. In genetic counseling terms, these resolving heart murmurs are important. Failure of equal and appropriate growth of the two ventricles may result from abnormal heart looping, abnormal inlet orifices, or obstruction of the outlet vessels. The most serious is failure of growth of the left ventricle, known as hypoplastic left heart (HLHS). Mutations in *HAND1* and *GJA1* have both been implicated in the development of HLHS (18). A more specific defect of development of the right ventricular muscular wall results in a distended saclike right ventricle with various names, including right ventricular dysplasia and Uhl anomaly.

TABLE 46-1

	Gene	Gene Function	Cardiac Anomalies	Other Reported Anomalies	Inheritance	
Laterality defects	ACVR2B	Member of transforming growth factor-beta (TGF-beta) superfamily of structurally related signaling proteins	Transposition of the great arteries, double-outlet right ventricle, ventricular inversion, aberrant systemic venous return	Polysplenia, asplenia, midline liver, malroation	AD	6
	CFC1	Member of the epidermal growth factor (EGF)- Cripto, Frl-1, and Cryptic (CFC) family. Plays key role in intercellular signaling pathways during vertebrate embryogenesis including left-right asymmetry in the heart.	Dextrocardia, right atrial isomerism, left atrial isomerism, transposition of the great arteries, double-outlet right ventricle, aberrant systemic venous return	Holoprosencephaly, agenesis of the corpus callosum, microcephaly, malrotation, polysplenia, asplenia, neural tube defects, pulmonary isomerism	AD, reduced penetrance	6 6
	CRELD1	Member of a subfamily of epidermal growth factor-related protein.	Atrioventricular septal defect, dextrocardia, double-outlet right ventricle	None	AD	6 6
	LEFTY2	Member of the TGF-beta family of proteins. Plays a role in left-right asymmetry determination of organ systems during development.	Hypoplastic left heart, atrioventricular septal defect, dextrocardia, aberrant systemic venous return	Malrotation, midline liver, polysplenia		6
	NODAL	Member of TGF-b superfamily. Plays a key role in specification and patterning in mammalian embryogenesis	DORV, transposition of the great arteries, total anomalous pulmonary venous return, partial anomalous pulmonary venous return, ASD, VSD, aortic coarctation, PDA	Holoprosencephaly, malrotation, asplenia, hydronephrosis	AR	2 6
	THRAP2	Putative member of the TRAP family involved in early embryonic patterning expressed in brain, heart, skeletal muscle, kidney, placenta, and peripheral blood leukocytes	Transposition of the great arteries, VSD, aortic coarctation	Mental retardation, microcephaly	AD, reduced penetrance	6 6
	ZIC3	Member of the ZIC family of C2H2-type zinc finger proteins. Functions as a transcription factor in early stages of left-right asymmetry.	Transposition of the great arteries, DORV, right atrial isomerism, total anomalous pulmonary venous return, PDA, aberrant systemic venous return	Asplenia, biliary atresia, vertebral anomalies, anal anomalies, malrotation,	X-linked	3 3 3

**TABLE 46-2 Nonsyndromic CHD**

Heart Defect	Gene	Gene Function	OMIM
Atrioventricular canal	CRELD1	Member of a subfamily of epidermal growth factor-related protein.	606217
	GDF1	Member of the bone morphogenetic protein (BMP) family and the TGF-beta superfamily. The members of this family are regulators of cell growth and differentiation in both embryonic and adult tissues. Studies suggest that this protein is involved in the establishment of left-right asymmetry in early embryogenesis.	600309
	GJA1	Member of the connexin gene family. Major protein of gap junctions in the heart that are thought to have a crucial role in the synchronized contraction of the heart and in embryonic development.	121014
Hypoplastic left heart	GJA1	Member of the connexin gene family. Major protein of gap junctions in the heart that are thought to have a crucial role in the synchronized contraction of the heart and in embryonic development.	121014
	HAND1	Part of a family of basic helix-loop-helix transcription factors. One of two HAND proteins asymmetrically expressed in the developing ventricular chambers. Working in a complementary fashion, they function in the formation of the right ventricle and aortic arch arteries.	241550
	HAND1	Part of a family of basic helix-loop-helix transcription factors. One of two HAND proteins asymmetrically expressed in the developing ventricular chambers. Working in a complementary fashion, they function in the formation of the right ventricle and aortic arch arteries.	241550
Septal defects	NKX2.5	Functions in early determination of the heart field and may play a role in formation of the cardiac conduction system	602406
	CITED2	Inhibits transactivation of HIF1A-induced genes by competing with binding of HIF1a to p300-CH1	108900
	GATA4	Family of zinc-finger transcription factors. Regulates genes involved in embryogenesis and in myocardial differentiation and function.	600584
	HAND1	Part of a family of basic helix-loop-helix transcription factors. One of two HAND proteins asymmetrically expressed in the developing ventricular chambers. Working in a complementary fashion, they function in the formation of the right ventricle and aortic arch arteries.	602937
	HAND2	Part of a family of basic helix-loop-helix transcription factors. One of two HAND proteins asymmetrically expressed in the developing ventricular chambers. Working in a complementary fashion, they function in the formation of the right ventricle and aortic arch arteries.	607941
	TBX20	Interacts physically, functionally, and genetically with other cardiac transcription factors, including NKX2-5, GATA4, and TBX5	241550
	ACTC1	Actins are highly conserved proteins that are involved in various types of cell motility and is major constituent of the contractile apparatus of the heart.	602406
	MYH6 THRAP2	Encodes the alpha heavy chain subunit of cardiac myosin. Putative member of the TRAP family involved in early embryonic patterning expressed in brain, heart, skeletal muscle, kidney, placenta, and peripheral blood leukocytes	602407
Double-outlet right ventricle	CFC1	Member of the epidermal growth factor (EGF)- Cripto, Frl-1, and Cryptic (CFC) family. Plays key role in inter-cellular signaling pathways during vertebrate embryogenesis including left-right patterning in the heart.	611363
	GDF1	Member of the bone morphogenetic protein (BMP) family and the TGF-beta superfamily. The members of this family are regulators of cell growth and differentiation in both embryonic and adult tissues. Studies suggest that this protein is involved in the establishment of left-right asymmetry in early embryogenesis.	612794
	NKX2.5	Functions in early determination of the heart field and may play a role in formation of the cardiac conduction system	160710

TABLE 46-2 Nonsyndromic CHD—Cont'd			
Heart Defect	Gene	Gene Function	OMIM
Tetralogy of Fallot	GATA4	Member of the GATA family of zinc-finger transcription factors. Thought to regulate genes involved in embryogenesis and in myocardial differentiation and function.	187500
	JAG1	Ligand for the receptor notch 1	600576
	NKX2.5	Functions in early determination of the heart field and may play a role in formation of the cardiac conduction system	187500
	ZFPM2/FOG2	Member of the FOG family of transcription factors. Modulates the activity of GATA family proteins.	601920
	GDF1	Member of the bone morphogenetic protein (BMP) family and the TGF-beta superfamily. The members of this family are regulators of cell growth and differentiation in both embryonic and adult tissues. Studies suggest that this protein is involved in the establishment of left-right asymmetry in early embryogenesis.	600584
Bicuspid aortic valve	NOTCH1	Member of the Notch family of proteins which function as a receptor for membrane bound ligands, and may play multiple roles during development	187500
Supravalvular aortic stenosis	ELN	Protein product is one of the two components of elastic fibers	603693
Transposition of the great arteries	CFC1	Member of the epidermal growth factor (EGF)- Cripto, Frl-1, and Cryptic (CFC) family. Plays key role in intercellular signaling pathways during vertebrate embryogenesis including left–right patterning in the heart.	109730
	GDF1	Member of the bone morphogenetic protein (BMP) family and the TGF-beta superfamily. The members of this family are regulators of cell growth and differentiation in both embryonic and adult tissues. Studies suggest that this protein is involved in the establishment of left–right asymmetry in early embryogenesis.	130160
	THRAP2	Putative member of the TRAP family involved in early embryonic patterning expressed in brain, heart, skeletal muscle, kidney, placenta, and peripheral blood leukocytes	185500
Aortic coarctation	THRAP2	Putative member of the TRAP family involved in early embryonic patterning expressed in brain, heart, skeletal muscle, kidney, placenta, and peripheral blood leukocytes	217095

Partitioning of the outflow tract begins during the fifth week. There are two pairs of ridges (bulbar and truncal) that fuse to form a spiral septum that separates the aortic and pulmonary outflow tracts. These ridges are derived from cardiac neural crest cells. Abnormal contributions of cells from the cardiac neural crest have been implicated in the 22q11 phenotype and ablation of the cardiac neural crest cells in chick embryos results in outflow tract and right ventricular hypoplasia (19). Complete failure of septation results in a common arterial trunk or, as it is more commonly known, persistent truncus arteriosus (Figure 46-4). This spiraling separation ultimately results

in placing the aorta on the left and the pulmonary artery on the right (Figure 46-5A–H). If this process is incomplete or distorted, the aorta overrides the upper margin of the ventricular septum; the membranous septum remains incomplete, and the outlet of the right ventricle is narrowed. These malformations combine to cause hypertrophy of the right ventricle. The combination of an aorta overriding a VSD with right ventricular outflow tract obstruction and right ventricular hypertrophy constitutes the tetralogy of Fallot (Figure 46-6). If the process is further distorted, the aorta lies predominantly over the right ventricle and the term double-outlet right

FIGURE 46-2

FIGURE 46-3

FIGURE 46-4

FIGURE 46-5

FIGURE 46-6

ventricle is applied (Figure 46-7). This anomaly may also form part of the spectrum that results in an abnormal plane of the outflow septum such that the anterior vessel becomes connected to the left ventricle and the morphologic aorta to the right ventricle. Transposition of the great arteries (TGA) is thus distinct from most outflow defects in that it results from a malformation of the septum rather than a neural crest migration anomaly. This distinction is reflected in the syndrome associations and recurrence risks (Figure 46-8).

Malformations involving the major vessels connected to the heart are generally included with heart defects in discussions of cause and recurrence risk. Systemic venous drainage is rarely of major genetic importance, although absence of the last segment of the inferior vena cava and its replacement by an azygous connection to the superior vena cava is a valuable diagnostic sign of lack of a morphologic right atrium in a left isomerism sequence. Abnormality of pulmonary venous drainage is of much greater significance. Four pulmonary veins rendezvous with an outgrowth from the back of the left atrium. The coalescence incorporates into the posterior wall, producing four separate orifices. If one or more orifices are displaced, the term anomalous pulmonary venous drainage is applied, which may be partial, involving up to three

FIGURE 46-7

FIGURE 46-8

FIGURE 46-9

vessels, or complete, when it is known as total anomalous pulmonary venous return (Figure 46-9).

The ductus arteriosus (arterial duct) connects the right ventricular outflow to the descending aorta (Figure 46-10C only). It is usually called the sixth aortic arch, but it is morphologically distinct and has evolved to have an oxygen-sensitive lining, which allows it to constrict and occlude after birth, allowing the pulmonary circulation to open. It often stays open after birth, particularly in preterm infants, in whom the duct is not mature. The persistent ductus arteriosus (PDA) is, therefore, one of the most common anomalies of the cardiovascular system in postnatal life, but an essential physiologic structure *in utero* (Figure 46-11).

This brief overview has focused on anomalies relevant to a group of major defects that are serious after birth but compatible with intrauterine survival. The dependence of the embryo and fetus on a functional circulation means that any systemic defect that compromises more generalized intrauterine structure, function or both causes loss at an early stage.

### 46.3 SPECIFIC SYNDROMES WITH CONGENITAL HEART DEFECT

It is not surprising given the complexity of cardiovascular embryology and the large number of genes involved in normal heart development that the list of syndromes associated with congenital heart defects is not short. Appendix 1-11 contains a list of well-researched syndromes as grouped by their cardiac malformation. This appendix draws heavily on the previous edition and is

recommended as a reference source for the evaluation of syndromic causes of congenital heart defects. Common syndromes are discussed in more detail in the following sections.

## 46.4 CHROMOSOMAL DISORDERS

Although the application of aCGH has quickly become the diagnostic screening test of choice, chromosome analysis continues to be clinically useful particularly as a prenatal screening test and in the patient with findings suggestive of an aneuploidy syndrome. We have highlighted in the next section those aneuploidy syndromes commonly encountered by the medical geneticist.

### 46.4.1 Trisomy 21 (Down Syndrome)

Down syndrome is one of the most common genetic syndromes, with an estimated birth prevalence of 1 per 700 live births (20). Clinical features can include midface hypoplasia, epicanthal folds, up-slanting palpebral fissures, Brushfield spots on the irides, single palmar crease, brachydactyly, and increased sandal gap (Figure 46-2). Approximately 40% of patients with Down syndrome will have a congenital heart defect and of these, almost half will have the otherwise rare atrioventricular septal defect (AVSD) (21). Tetralogy of Fallot occurs in 10–15%. To date, no single gene or set of genes on chromosome 21 has been shown to cause heart defects in Down syndrome. Recently, mutations in *CRELD1* have been identified in patients with Down syndrome and AVSD, implicating *CRELD1* mutations, together with Trisomy 21 and possible environmental factors, as a risk susceptibility gene (22). For additional information on Trisomy 21, see Chapter 43.

### 46.4.2 Trisomy 18 (Edwards Syndrome)

Trisomy 18 is the second most common autosomal aneuploidy after Down syndrome. This is an important

bedside diagnosis to confirm due to the very poor prognosis and markedly diminished life expectancy that may influence medical management. Interestingly, recent studies have suggested that aggressive management is becoming more common, despite this well-recognized poor prognosis. The craniofacial manifestations of an infant with Trisomy 18 may be subtle, but typically include: prominent occiput, low-set ears, micrognathia, small palpebral fissures, short sternum and typical finger clenching (Figure 46-7). Heart defects are a recognized association and are a cause of early demise. Heart defects are often more complex in boys than in girls with Trisomy 18 and associated with increased mortality (23). For additional information on Trisomy 18 see Chapter 43.

### 46.4.3 Trisomy 13 (Patau Syndrome)

The birth incidence of Trisomy 13 is about one in 7000. Survival beyond the first year of life is rare (24). The characteristic clinical features are postaxial polydactyly, cleft lip and palate (often bilateral and severe), and hypotelorism associated with holoprosencephaly (Figure 46-9–46-11). There is a high incidence of cardiac defects, in particular atrial septal defects and VSDs. Disturbance of cardiac position, including dextrocardia, is common, suggesting a role for a gene or genes on chromosome 13 in laterality development (25). Appropriate identification of Trisomy 13 is important for recurrence risk counseling as well as directing clinical management, as aggressive medical interventions are not recommended given the high mortality rate and poor prognosis in long-term survivors. For additional information on Trisomy 13, see Chapter 43.

### 46.4.4 Turner Syndrome (Ulrich Turner Syndrome)

Turner syndrome has a birth prevalence of about 1 in 1850 live female births. In addition, a large proportion of affected fetuses are lost as early miscarriages, many of which can be attributed to the presence of a severe congenital heart defects, particularly HLHS (12). For live births, about 10% of Turner syndrome females have a clinically evident heart defect, with an additional 10% having an anomaly on echocardiogram, such as a bicuspid aortic valve. The most common abnormality is bicuspid aortic valve (16%) and coarctation of the aorta (11%); however, structural defects such as PAPVR and atrial and VSDs are also seen (26). And while the congenital heart defect may be detected and repaired in childhood, all patients with Turner syndrome require life-long cardiac follow-up because of the potential for progressive dilatation of the ascending aorta and an increased risk of thoracic aortic dissection (27). Additional findings are variable and include short stature, gonadal dysgenesis, and a variable dysmorphic appearance with neck webbing (pterygium

FIGURE 46-10

colli), down-slanting palpebral fissures and low-set ears (Figure 46-1–46-2). Patients with ring X chromosomes are at risk for mental retardation although classic Turner patients can struggle with learning disabilities. For additional information, see Chapter 44.

### 46.5 MICRODELETIONS/ MICRODUPLICATION SYNDROMES

Advances in molecular cytogenetic technology have significantly increased the ability to detect smaller and smaller chromosomal imbalances. This includes both

FISH and, more recently, aCGH, which has quickly become the most important diagnostic screening tool in patients with congenital heart disease who do not have a genetic syndrome readily identified by clinical examination (28). Although the identification of copy number variants of unknown clinical significance has been a significant limitation of CGH, this technology has been instrumental in defining the loss or gain of chromosomal material with such detail as to permit knowing which gene/s are involved. This has led to further identification of genes that may have critical roles in both syndromic and nonsyndromic congenital heart defects.

FIGURE 46-11

### 46.5.1 22q11 Deletion Syndrome

22q11 deletion syndrome is the most common human chromosomal deletion syndrome occurring in approximately one per 4000–6000 live births (29). Clinical features include learning impairments, palate anomalies (including velopharyngeal insufficiency), characteristic facial appearance (Figure 46-12 but 52-11 from previous version), neonatal hypocalcemia, thymic hypoplasia, and immune deficiencies. Approximately 15% of cases are familial segregating as an autosomal dominant trait with marked variability. Although the deletion is visible by routine G-banded cytogenetic testing in some, about two-thirds of cases require FISH testing to confirm the diagnosis. Therefore, a clinical suspicion is required. The most commonly reported heart defects include tetralogy of Fallot, tetralogy of Fallot with pulmonary atresia, VSD, interrupted aortic arch (type B), and truncus arteriosus (30). Individuals with a cardiac defect and an anomaly of the aortic arch are more likely to harbor a 22q11 deletion than those with other heart defects such as double-outlet right ventricle or TGA. 22q11 deletions are rarely identified in such non-conotruncal defects (7). Most individuals with 22q11 deletion syndrome harbor either a 3- or 1.5-Mb deletion in 22q11.22. This region includes *TBX1*, which has emerged as a major genetic determinant of the 22q11 deletion phenotype (31). Point mutations in *TBX1* occur in patients with findings suggestive of the 22q11 deletion syndrome phenotype but with normal FISH studies. Appropriate identification of the cardiac patient with a 22q11 deletion is important to facilitate identification of associated anomalies, renal defects, and possible calcium abnormalities. In

addition, a higher operative mortality may exist in those individuals with a 22q11 deletion (32).

### 46.5.2 Williams Syndrome

Williams syndrome, or Williams–Beuren syndrome, is characterized by learning disability with a unique personality profile: a “cocktail party” personality with a readiness to converse in a friendly outgoing fashion but with little content. The dysmorphic features are easily recognized and include: malar flattening, periorbital fullness, heavy sagging cheeks, short nose, poorly developed Cupid’s bow on the upper lip, and everted lower lip (Figure 46-13, Figure 52-9 from previous edition). The cardinal cardiovascular malformation in this syndrome is supravalvular aortic stenosis (SVAS), which affects about one-third of cases and tends to be progressive with age. Less well-recognized and more difficult to detect are peripheral pulmonary artery stenoses, which produce murmurs over the lung fields. The striking association with SVAS, which had been described as an isolated autosomal dominant trait, prompted the speculation that Williams syndrome would turn out to be a deletion involving the gene responsible for SVAS (33). The identification of a balanced translocation associated with SVAS provided an additional clue. Curran and associates first showed that dominant SVAS mapped to chromosome 7 at a translocation breakpoint and, subsequently, that most Williams syndrome cases could be shown to have a deletion of this region of chromosome 7 (34). The gene encoding tropoelastin (ELN) was shown to be causative in isolated SVAS by the demonstration of loss-of-function mutations (35,36).

FIGURE 46-12

### 46.5.3 Alagille Syndrome

Alagille syndrome is characterized by hypoplasia of the intrahepatic bile ducts, leading to a variable degree of cholestasis, which may present with neonatal jaundice or become apparent later in life (37). Up to 90% of affected probands have single or multiple areas of peripheral pulmonary artery stenosis. In about one-third, a variety of other intra- and extracardiac malformations are seen. The face is mildly dysmorphic, with a prominent forehead, deep-set eyes, and thin nose (Figure 46-14, 46-10 from previous edition). Other typical clinical features include skeletal defects (particularly butterfly vertebrae) and anterior chamber eye defects, confusingly called posterior embryotoxon. Externally, the striking feature is a pale ring around the iris known as arcus juvenilis (Figure 46-15) (38). A microdeletion of 20p12, which includes JAG1, is demonstrable in 7% of cases. JAG1 is part of the Notch signaling pathway and point mutations are responsible for the phenotype in approximately 89% of cases; mutations in NOTCH2 account for approximately 1% of cases (39).

## 46.6 SINGLE-GENE DISORDERS

Chromosome analysis, FISH, and CGH are useful diagnostic tools in the evaluation of syndromic causes of congenital heart defects. However, these technologies are not able to detect abnormalities at the single-gene level. So, if they are used without recognition of the single-gene causes of many syndromic congenital heart defects, important diagnoses will be missed. A few of these syndromes are highlighted in the following section.

### 46.6.1 Noonan Syndrome

One of the best-recognized syndromes in the pediatric cardiology clinic is Noonan syndrome. Earliest

descriptions have been traced back over a century, but the syndrome derives its name from the report by Noonan and Ehmke in 1963 of nine children with valvar pulmonary stenosis, short stature, mild learning difficulties, and dysmorphic appearance. The mother and two daughters in Figure 46-16 (Figure 46-12 from previous edition) illustrate the variable phenotype. Collectively they have the full picture, yet none has the complete pattern.

In infancy, the striking features are the hypertelorism, down-slanting eyes with low-set, posteriorly rotated ears, and low posterior hairline. Later, the face becomes more triangular and rather coarse in appearance. In adulthood, the eyes are less prominent and the nose has a thinner bridge and pinched root with wide base; the neck becomes longer, accentuating the prominent trapezius

FIGURE 46-14

FIGURE 46-13

FIGURE 46-15 Posterior embryotoxon is an anteriorly displaced Schwalbe's line (the most peripheral edge of Descemet's membrane).

and/or neck webbing, which caused original confusion with Turner syndrome in the literature. Other important features are the feeding difficulties of infancy, a characteristic anterior chest deformity, wide spaced nipples, cryptorchidism, a predisposition to lymphatic dysplasia and bleeding diathesis, and a high frequency of nevi and café-au-lait macules.

Two-third of children with Noonan syndrome have a heart defect, with valvar pulmonary stenosis in 50%. Often the valve is dysplastic, making balloon dilation more difficult. Among a variety of other defects reported, the most frequent are ASD, asymmetrical septal hypertrophy, and PDA; VSD occurs in about 5% (40,41). The electrocardiogram typically shows left axis deviation with a wide QRS complex, giant Q waves, and a negative pattern in the left precordial leads (42). There is a phenotypic overlap with a number of syndromes, particularly LEOPARD syndrome (an allelic disorder with mutations in *PTPN11*), neurofibromatosis type 1, Costello syndrome, and cardiofaciocutaneous syndrome. Noonan syndrome is genetically heterogeneous disorder due to dysregulation of the Ras/MAPK (mitogen-activated protein kinase) signal transduction pathway. The Ras/MAPK pathway is implicated in growth factor-mediated cell proliferation, differentiation, and cell death. Over nine genes have been identified in association with altered Ras/MAPK signaling with resulting overlapping phenotypes. Mutations identified in *PTPN11*, *SOS1*, *RAF1*, and *KRAS* are responsible for the Noonan syndrome phenotype. Some genotype/phenotype correlations exist; for example, hypertrophic cardiomyopathy is a complication in about 20% of patients with Noonan syndrome, and more frequent in patients with *RAF1* mutations. However, there is insufficient evidence to correlate genotype with occurrence of a specific type of congenital heart defect (43).

Life-long cardiac follow-up is important for adults with Noonan syndrome as left-sided obstructive

lesions may develop in adulthood. Pulmonary valve insufficiency and right ventricular dysfunction are also potential problems after early pulmonary valve surgery (44).

## 46.7 HOLT-ORAM SYNDROME

Holt-Oram syndrome is the best-recognized of the heart-hand syndromes and is caused by mutations in the gene encoding T-box transcription factor *TBX5*. The characteristic anomalies are underdevelopment of the shoulder girdle with triphalangeal thumb and ASD (45) (Figure 46-17, Figure 46-13 from previous edition). The limb defects can vary from phocomelia to minor anomalies of joint movement at the thumb, elbow, or shoulder. About half of gene carriers have a secundum ASD, with occasional reports including VSD, AVSD, and truncus arteriosus. Patients may also present with mild to severe cardiac arrhythmias, commonly atrioventricular block (46).

## 46.8 CHARGE SYNDROME

CHARGE is a mnemonic that stands for coloboma, heart defects, choanal atresia, retarded growth and development, genital abnormalities, and ear anomalies. Formerly an association, the specific developmental anomalies of the optic vesicle, otic capsule, midline CNS structures, and upper pharynx have been attributed, in the majority of cases, to mutations in *CHD7*. Updated diagnostic criteria for CHARGE have been proposed and emphasize the importance of additional findings, for example, anomalies of the semi-circular canals, not included in the mnemonic (47). Congenital heart defects are seen in approximately 75% of children diagnosed with CHARGE syndrome, with tetralogy of Fallot or Fallot spectrum being the most common (48,49) (Figure 46-18).

FIGURE 46-16

FIGURE 46-17

### 46.8.1 Heart Malformation and Metabolic Disorders

The inborn errors of metabolism, such as the mucopolysaccharidoses (discussed in Chapter 102), develop cardiac involvement as a postnatal event, particularly involving valve dysfunction due to deposition of storage material and, most dramatically in type 2 glycogenosis or Pompe disease, with accumulation of material in the cardiac muscle. Some metabolic defects are not corrected by the maternal influence and can produce congenital malformations that may include the heart. Two are worthy of mention, since simple diagnostic biochemical tests exist, which facilitates prenatal diagnosis.

### 46.9 ZELLWEGER SYNDROME

Zellweger (cerebrohepatorenal) syndrome was originally described as a lethal multiple malformation syndrome of infancy characterized by profound hypotonia, a marked paucity of facial movement, open anterior fontanelle, hypoplastic supraorbital ridges, and a broad nasal bridge (Figure 46-19, Figure 46-15 from previous edition). Hepatomegaly, renal cortical cysts, deafness, cataracts, and calcific stippling of the patellae complete the typical phenotype. The discovery of a peroxisomal defect in a child with this syndrome emphasized that this pattern represents one end of a clinical spectrum that may result from at least 10 genetic defects in peroxisomal

assembly or the function of the single matrix enzymes, including PEX1, on chromosome 7q (50). Peroxisomes are single-membrane-bound organelles present in virtually all eukaryotic cells. They are involved in numerous metabolic processes, both anabolic and catabolic, including  $\beta$ -oxidation of very-long-chain fatty acids, the basis of the standard diagnostic test (51). Severe cerebral dysfunction results from premature arrest of migrating neuroblasts. Thymic hypoplasia and outflow tract cardiac malformations occur (52).

### 46.10 SMITH-LEMLI-OPITZ SYNDROME

Smith-Lemli-Opitz (SLO) syndrome is characterized by severe learning disability, failure to thrive, cleft palate, hypospadias in males, and 2/3 syndactyly. The facies are dysmorphic, with bi-temporal narrowing and anteverted nares (Figure 46-20, Figure 46-16 from previous edition). In one series, 16% of patients with SLO were found to have an AVSD, 7% with TAPVR (53).

The discovery that affected individuals have hypocholesterolemia and markedly elevated levels of 7-dehydrocholesterol due to a defect in the 7-dehydrocholesterol reductase gene showed that another multiple malformation syndrome had a metabolic basis (54). By 2003, 91 different pathologic mutations had been reported in the gene (55). How and why a defect in the cholesterol biosynthesis pathway should have such an adverse effect on, for example, the septation of the ventricular inlet

FIGURE 46-18

remains to be established, but from the practical perspective, the possibility of SLO syndrome must be considered in a dysmorphic infant with a heart defect in view of the recessive mode of inheritance and the availability of pre- and postnatal diagnostic tests.

### 46.10.1 Genes Responsible for Congenital Heart Malformations as Mongogenic Traits

Although congenital heart defects rarely occur in the context of large families, there are some case reports of heart malformations segregating as a monogenic trait. Coarctation of the aorta, interrupted aortic arch, and hypoplastic left heart have been identified in multigenerations with clinical variability and reduced penetrance (56,57). Overall, only a small number of single-gene causes of isolated heart defects have been identified, suggesting that congenital heart defects in general are extremely heterogeneous and genetically complex (Table 46-2). The investigation of genomic disorders due to the deletion of one or more genes and traditional mapping have identified the location, and in some cases the identity, of genes that, when defective, can produce isolated heart defects. The classic examples are *ELN* as

a cause of SVAS and *JAG1* leading to peripheral pulmonary artery stenosis. In addition, mapping studies and candidate gene analysis led to the discovery of *ZIC3* as a cause of X-linked laterality syndrome (Table 46-1), and the same approach yielded *TFAP2B* as the cause of autosomal dominant PDA (58). Mutations in *GATA4* and *CRELD1* have been identified in patients with isolated AVSD (59,60).

### 46.10.2 Environmental Causes and the Teratogen Syndromes

The search for specific environmental associations of congenital heart defects has scored notable successes. This began with congenital rubella, once a major cause of congenital heart defects, has now receded in most developed countries in which maternal vaccination is widespread. Table 46-3 lists several teratogens that are well-recognized as causes of congenital heart disease. In general terms, the evidence for a major contribution from specific environmental exposures is not strong (61). In practical terms, maternal diabetes and alcohol abuse remain the most important external threats to normal heart development, but it is important to take a history of drug ingestion before offering recurrence risks. This is important when the consultation is with an affected individual, since recognition of a teratogenic cause enables the counselor to give a very small recurrence risk. This assumes, of course, that it is possible to remove the cause in the next pregnancy.

FIGURE 46-19

FIGURE 46-20

### 46.11 MATERNAL DIABETES

Fetuses born to mothers with diabetes mellitus are at a five-fold increased risk of birth defects, of which congenital heart defects are the most common. Defects in laterality, looping, and conotruncal septation predominate, suggesting that exposure in utero may affect cardiogenesis as early as 7-week gestation (62). The risk of fetal congenital abnormalities in pregnant women with diabetes mellitus is related to the level of glycemic control in early pregnancy; thus, strict metabolic targets as close to normal glycosylated hemoglobin (HbA1c) (ie, 4.0%-6.0%) are recommended (63). The mechanism of this

TABLE 46-3 Some Common Teratogens		
Teratogenic Influence	Risk of Heart Defect (%)	Most Common Type
Maternal rubella	35	PDA, peripheral pulmonary artery stenosis, septal defects
Maternal diabetes	3–5	VSD, coarctation, TGA
Maternal phenylketonuria	25–50	Tetralogy of Fallot
Systemic lupus erythematosus	20–40	Complete heart block
Maternal alcohol abuse	25–30	Septal defects
Hydantoin	2–3	Pulmonary and aortic stenosis, coarctation of aorta, PDA
Trimethadione	15–30	Tetralogy of Fallot, TGA, hypoplastic left heart
Thalidomide	<5	Tetralogy of Fallot, septal defects, truncus arteriosus
Lithium		Ebstein anomaly, tricuspid atresia, ASD
Retinoic acid	10–20	Conotruncal heart defects
Cocaine	5	Excess situs disturbance

relationship is poorly understood, however emerging evidence suggests that mutations in *RasGRP3* contribute to the developmental defects in mouse embryos born to diabetic mothers by affecting endothelial cell migration (64).

### 46.12 MATERNAL CIGARETTE SMOKING

There is growing evidence to suggest an increased risk of congenital heart defects due to fetuses exposed to toxins from tobacco. Maternal smoking during pregnancy has been associated with septal and right-sided obstructive defects as well as intrauterine growth retardation (65). However, other studies show conflicting risks (66). In the United States, an estimated 28% of reproductive-aged women smoke cigarettes, and a significant portion of those women continue to smoke during pregnancy (67). Therefore, an investigation of maternal tobacco use before and during pregnancy may provide insight to the pathogenesis of certain congenital heart defects and counseling opportunity for future risk prevention.

### 46.13 MATERNAL DRUG INGESTION

#### 46.13.1 Alcohol

Alcohol is the non-therapeutic drug most frequently ingested by pregnant women. Alcohol induces heart defects in some exposed fetuses; VSD is most common, but ASD, tetralogy of Fallot, and other defects can also occur (68). Fetal alcohol syndrome produces a recognizable phenotype, but the facial characteristics may not be present in all affected children (Figure 46-21, Figure 46-17 from previous edition). The overall incidence of fetal alcohol syndrome in the general population may be 0.1 to 3.3 per 1000, with cardiovascular defects present in 28% of affected infants (68). TGA may be more common in infants exposed to alcohol (66). Heavy alcohol drinkers, defined as women consuming a

FIGURE 46-21

daily average equivalent of 45 mL (1.5 oz) or more absolute alcohol, had offspring with a higher incidence of major anomalies compared to more moderate drinkers. A “safe” level of alcohol intake during pregnancy has not been established and alcohol exposure prenatally remains an important cardiac teratogen.

### 46.13.2 Cocaine

Prenatal cocaine exposure affects the developing heart including an increased rate of arrhythmias and cardiac defects associated with heterotaxy. Fetal cocaine exposure in animal models suggests epigenetic alterations with long-term consequences in the offspring, even in the absence of gross malformations (69). More studies are needed to understand better both the short- and long-term consequences of prenatal cocaine exposure.

### 46.13.3 Lithium

Lithium, used in the treatment of depression, was first recognized as a teratogen because of the increased number of infants born with Ebstein anomaly, a relatively rare defect of the tricuspid valve. One study of infants exposed to lithium in utero found high rates of malformations with congenital heart defects accounting for the vast majority. Of these infants nearly half had Ebstein anomaly plus other cardiac malformations (70). However, more recent studies have failed to confirm this high risk.

### 46.13.4 Maternal Phenylketonuria

Successful treatment of phenylketonuria through newborn screening and dietary modification means homozygous females of normal intellect reach child-bearing age (71). A woman who has abandoned the dietary restrictions may enter pregnancy with high blood levels of phenylalanine, which are associated with microcephaly and mental retardation in around

90% of offspring. In addition, congenital heart defects are present in 12% pregnancies in untreated mothers, commonly tetralogy of Fallot, aortic coarctation, and HLHS (72).

## 46.14 FOLIC ACID SUPPLEMENTATION

Folic acid supplementation reduces by over one-half the number of neural tube defects in offspring. A less well-recognized effect is a probable reduction in conotruncal heart malformations. One study reported a 52% reduction in heart defects (73). Additional studies are needed to prove efficacy. The decision of the United States to supplement flour supplies will provide further evidence on this issue in coming years.

### 46.14.1 The Adult with Congenital Heart Defect

Advances in cardiac imaging, cardiac catheterization, electrophysiology, and improving surgical techniques have resulted in the exponential growth of the population of adult patients with congenital heart defects, both syndromic and isolated ones. As this population transitions from the care of the pediatric provider to the adult provider, it is important for members of the medical team to appreciate the specific needs unique to this population of patients. Long-term follow-up has identified patients with previously undiagnosed syndromes that are presenting later in life. For example, mouse models of *NKX2.5* mutations develop arrhythmias and abnormal contractility as adults (74). An accurate genetic diagnosis can provide anticipatory rather than reactive guidance that allows the medical team to be proactive in the care of the adult with congenital heart defects rather than reactive.

Studies on adult patients with more common genetic syndromes is emerging and personalization of their care to their unique medical needs, depending on specific diagnosis, is necessary to prevent significant morbidity and mortality (75). Table 46-4 is an excerpt

**TABLE 46-4** Recurrence Rates in Offspring of Males and Females with Heart Defects

Authors	Defect	% Offspring Affected		
		Male	Female	Ratio F:M
Williamson (532)	ASD	0	11.1	
Taussig et al. (476)	Tetralogy of Fallot	0	3.1	
Zetterqvist (552)	ASD, PDA, coarctation	1.6	3.1	1.94
Dennis and Warren (115)	Pulmonary valve stenosis, pulmonary	3.0	2.9	0.97

from a recent review exploring the history and management of the adult patient with a genetic syndrome diagnosis.

Pregnancy represents a major challenge for the woman with coexisting congenital heart defects. Discussions about the risks of pregnancy, including the impact of heart disease on fertility, recurrence risks and potential teratogenic effects from medications should be considered around reproductive age. For syndromes such as Turner and Marfan, guidelines exist to help direct clinical management of the pregnant patient (76,77). For those with other congenital heart defects, less information is available. Pregnancy related risks could include increased risks for thromboembolism, heart failure, arrhythmias and dissection depending on the specific heart lesion (78). Studies on pregnant patients with tetralogy of Fallot have reported higher rates of mortality, prematurity and intrauterine growth restriction in offspring (79).

#### 46.15 EMPIRICAL RISKS FOR SIBS OF CHILDREN WITH ISOLATED HEART DEFECTS

Table 46-5 (Table 46-3 from previous edition) reviews the major traditional studies of recurrence risk in sibs of children with heart defects. The general principle that sib risks fall into the range of 2–5%, so often used by genetic counselors, is apparent. Most of the studies did not distinguish between sibs born before and after the proband, which may have distorted figures, since families who have had a child with a heart defect may be less likely to have additional children. Nevertheless, the counseling figures shown are sufficient in practical terms, since the advances in fetal echocardiography and postnatal care of affected children have improved to the point where it is reasonable to counsel in terms of the risk of recurrence being small.

#### 46.16 EMPIRICAL RISKS FOR OFFSPRING

In early studies of recurrence risks in the offspring of adults born with major heart defects, the limited available literature suggested a recurrence risk in offspring of 3–5%, comparable to sibs and compatible with a multi-factorial model of inheritance. However, studies have shown a much higher risk of congenital heart defects in offspring of parents with various congenital heart defects, in the range of 10–16% (80,81,82).

Although these higher offspring risks are now widely quoted, the possibility of selection bias cannot be excluded. Additional confounded factors include studies evaluating recurrence risks of different heart defects with some studies identifying an overall risk of 4% (83). In all, multiple studies report varying results and Table 46-6 (Table 46-4 from previous edition) summarizes this literature.

##### 46.16.1 Future Developments

As technology continues to drive discoveries in clinical genetics, the ability to identify genetic changes and their associated risk for birth defects will become routine in the medical genetics clinic. Completion of the Human Genome Project and the increasing affordability of whole genome sequencing and its interpretation will drive our understanding of key developmental pathways to identify genetic determinants of congenital heart defects. The future will involve a large-scale collaborative effort to bring together the necessary clinical resources to permit evaluation of the contribution of these genes and ultimately drive the personalization of medicine. The coming decade will bring greater understanding of the genetic contribution to congenital heart disease creating better treatment options and better outcomes; prevention outside the prenatal clinics, will have to wait much longer.

**TABLE 46-6 Common management issues for adults with genetics syndromes and cardiovascular. Abnormalities: Genetic**  
**primary care providers<sup>a</sup>**

Syndrome	Heart Defect	Complications (Postoperative Unless Specified)	Management
Chromosome Abnormality			
22q11.2 deletion	Interrupted aortic arch type B	Left ventricular outflow tract obstruction. Residual coarctation.	Depending on degree of obstruction, surgical correction may be required.
	22q11.2 deletion	Right ventricular outflow tract obstruction or insufficiency. Truncal right ventricular, or truncal valve regurgitation and stenosis.	Depending on the degree of obstruction, surgery may be required, e.g., aortic valve replacement.
	Tetralogy of Fallot	Right ventricular outflow tract obstruction, including pulmonary regurgitation, right ventricular dilation.	Depending on degree of obstruction, surgery may be required.
Down syndrome	Complete AVC <sup>b</sup>	Common atrioventricular valve regurgitation or stenosis.	Depending on degree of regurgitation, surgery may be required.
		Residual shunt at the site of the septal defect closure.	Depending on size of shunt or regurgitation, surgery may be required.
	Arrhythmia	Postoperative bradycardia, syncope	Monitor all cases. May need pacemaker.
	Mitral valve prolapse, less frequently aortic and tricuspid prolapse. Coronary artery disease	Usually asymptomatic. Mitral, aortic and tricuspid regurgitation may develop Not known to have increased risk of angina or myocardial infarction.	Auscultation in all individuals; echocardiography if abnormal. Routine population screening.
Turner Syndrome	Bicuspid aortic valve	Can progress to aortic stenosis. As in general population, there is associated risk of aortic dilatation, aneurysm and rupture.	Monitor all cases with meticulous echocardiography or MRI.
	Coarctation	Residual obstruction at the site of coarctation repair may lead to hypertension. Some mild coarctation may go undetected until adulthood. Repaired or unrepaired, associated with risk of aortic dilatation, dissection, and rupture.	Depending on severity of obstruction, anti-hypertensive medication, catheterization or surgical repair may be required. Meticulous imaging using echocardiography or MRI.
	Hypertension	Can be mild to severe.	Seek underlying cause, e.g., an aortic aneurysm, and treat aggressively when hypertension is present. Hypertension is a risk factor for aortic dissection.
	Aortic root dilation	Aortic dissection and rupture area associated with dilatation, although the natural history from dilatation to dissection has not been completely delineated. Beta-blockade can be useful.	Baseline imaging of aorta should be performed; at least one MRI examination should be provided to provide optimal imaging. In some cases, surgery may be indicated.
	ECG abnormalities	Aside from predisposition to resting tachycardia, not known to have pathologic arrhythmias.	Because of observed cardiac conduction abnormalities, avoid drugs that prolong QT interval.
Williams–Beuren Syndrome	Supravalvar aortic stenosis, focal or diffuse	Residual left ventricular outflow tract obstruction	Depending on degree of obstruction, surgery may be needed.
	Long-segment stenosis/hypoplasia Of thoracic or descending aorta ("coarctation")	Re-stenosis interventional catheterization	Depending on severity of obstruction, anti-hypertensive medication, catheterization or surgery may be required.
	Coronary artery stenosis (due to medial hypertrophy or dysplastic Aortic valve leaflet)	Coronary insufficiency	Screen coronary patency by echocardiography (if indicated), CTA, MRA or catheterization (if indicated).
	Hypertension Pulmonary artery stenoses (PPS, main branch stenoses)	Can occur at any age. Treat with antihypertensive medication. Balloon dilatation or stenting for significant obstruction. Complications such as tears or aneurysms reported.	Exercise stress testing is of limited value. Screen for renovascular cause.

Gene Abnormality			
Holt–Oram Syndrome	ASD, secundum-type, VSD, membranous, muscular	Residual shunt, rarely hemodynamic risk. Potential for stroke.	Depending on size of shunt, management
	ASD, secundum-type, VSD, Membranous, muscular	Eisenmenger syndrome	Medication for pulmonary hypertension
	Conduction block	Can be progressive; when complete heart block is present, may be associated with atrial fibrillation.	Need regular monitoring with Holter monitoring in those with known conduction system disease for development and/or progression; may require permanent pacemaker; anticoagulants (for atrial fibrillation)
Marfan Syndrome	Marfan Syndrome	Aortic dissection, rupture aortic regurgitation	Prophylactic aortic root repair (if >50 mm); valve sparing techniques
	Aortic dilatation	Progressive dilatation, rupture	Prophylactic grafting of any portion at risk; risks of surgery are less than medical, or in the case of end-stage disease, pain.
	Mitral valve prolapse	Mitral regurgitation, heart failure	Mitral valve repair or replacement
TGF- <i>B</i> receptor syndromes	Aortic dilatation	Aortic dissection, rupture	Prophylactic aortic root repair (if >40 mm using aortic diameter criteria for Marfan syndrome (>40 mm in adult))
	Aneurysm of other major arteries	Arterial dissection, rupture	Prophylactic repair
Hereditary Hemorrhagic Telangiectasia	Pulmonary arterio-venous malformations	Cyanosis; paradoxical embolization leading to stroke or brain abscess	Therapeutic or prophylactic embolization of coils when the diameter of the lesion is >10 mm or greater
	Hepatic arteriovenous malformations	Cirrhosis; hepatic encephalopathy	Medical management of liver disease
Noonan Syndrome	Pulmonic stenosis	Can present in adulthood for the first time; those with previous surgery or balloon angioplasty in childhood can have residual PS and/or pulmonary insufficiency	Options for severe pulmonary stenosis include valvuloplasty or valve replacement; pulmonary insufficiency often requires medical management
	ASD, secundum type	Residual shunt after repair in childhood; some adults have undetected large defect and fatigue symptoms; in combination with pulmonary stenosis may have risk for stroke	Depending on size of shunt may require closure by a septal occluder
	Hypertrophic cardiomyopathy	Right ventricular outflow obstruction; can coexist with a CHD such as pulmonary stenosis; risk of arrhythmias	Treatment considerations include beta blockers; careful monitoring; may also include treatment such as defibrillator

ASD, atrial septal defect; AVC, atrioventricular canal defect; CAVC, complete atrioventricular canal; CHD, congenital heart defects; CTA, CT angiography; ECG, electrocardiography

<sup>a</sup>Guidelines provide general information for primary care providers, but individuals require specific management by cardiologists. In the interest of brevity, each cardiac abnormality is not discussed in detail.

<sup>b</sup>ASD, VSD and tetralogy of Fallot were not discussed. Antibiotic prophylaxis for subacute bacterial endocarditis should be offered in appropriate doses per standard practice.

Lin, A. E., C. T. Basson, et al. (2008). "Adults with genetic syndromes and cardiovascular abnormalities: clinical history and management." *Genet Med* 10(7): 469–494.

APPENDIX

The following tables list syndromes in which a heart malformation may occur as grouped by the major heart defect. Space does not allow for every case report or occasional observation. Omim, GeneReviews and the Oxford Dysmorphology Database are excellent resources. In this table, GeneReviews are included where app. Several syndromes appear in more than one table.

Cardiac Defect <sup>a,b</sup>	Syndrome Name	Cardinal Features	Etiology	Inheritance	OMIM	Gene Reviews
AVSD	CHARGE	Colobomata (iris and/or retina, heart defects, atresia choanae, retardation of growth and development and/or central nervous system anomalies, genital hypoplasia in males, ears cup shaped and hearing loss (pulmonary valve stenosis)	CHD7 gene	AD	214800	Click link
	Down	Hypotonia, mental retardation, up-slanting palpebral fissures, epicanthal folds, brachycephaly, single palmar crease	Trisomy 21	Nondysjunction, unbalanced robertsonian translocations	190685	
	Ellis–Creveld	Short stature, postaxial polydactyly, miso/ acromelic shortening of limbs, short ribs,	EVC1 and EVC2	AR	225500	
	FG	Macrocephaly (absolute and relative), congenital hypotonia, small ears, agenesis of the corpus callosum, constipation, mental retardation	MED12	X-linked	305450	Click link
	Ivemark?	Postaxial polydactyly, hydrometrocolpos	MKKS	AR	236700	Click link
	McKusick-Kaufman Noonan	Short stature, pectus excavatum/carinatum, hypertelorism, low-set ears, mild mental retardation	PTPN11, SOS1, KRAS, RAF1	AD	163950	Click link
	Smith–Lemli–Opitz	Mental retardation, failure to thrive, feeding, difficulties, premature death, microcephaly, micrognathia, ptosis, anteverted nostrils, 2/3 syndactyly of toes, broad alveolar ridges, short stature, genital anomalies; occasional, polydactyly, cleft palate, various other, visceral malformations, cataract	DHCR7	AR	270400	Click link
Bicuspid aortic valve	1q21.1 microdeletion	Microcephaly, mild facial dysmorphism, autism, various heart defects	1q21.1 deletion	AD, reduced penetrance	612474	Click link
	17q21.31 deletion	Mental retardation, hypotonia, and characteristic face	Deletion 17q21.31	AD	610443	Click link
	9q subtelomeric deletion (Kleefstra)	Moderate to severe mental retardation, hypotonia, facial dysmorphisms, urogenital defects, seizures, behavior problems	9q34.3 deletion resulting in haploinsufficiency of EHMT1	AD, sporadic	610253	

	Beals	Arachnodactyly, large joint contractures, camptodactyly, "crumpled" ears, kyphoscoliosis,	FBN2	AD	121050	Click link
	Cranioectodermal dysplasia-1	Sagittal craniosynostosis facial dysmorphism, ectodermal and skeletal anomalies	IFT122	AR	218330

	Lymphedema-Distichiasis	Distichiasis, late-onset lymphedema; occasional cleft palate, micrognathia, pterygium colli, ptosis, Arnold–Chiari malformation, urinary tract malformations, spinal extradural cysts, vertebral anomalies, double uterus	FOXC2	AD	153400	<a href="#">Click link</a>
	McKusick–Kaufman	Postaxial polydactyly, hydrometrocolpos	MKKS	AR	236700	<a href="#">Click link</a>
	Microcephalic osteodysplastic primordial dwarfism (MOPD) I	Primordial dwarfism	Unknown	AR	210710	
	Microphthalmia-9	Bilateral microphthalmia, IUGR, short stature, bilateral pulmonary hypoplasia/ agensis, diaphragmatic hernia, mental retardation, hypotonia, early death	STRA6	AR	601186	
	Miller–Dieker	Lissencephaly type I, severe retardation, seizures, growth failure, tall furrowed forehead, bi-temporal narrowing, short upturned nose,	Deletions at 17p13.3 including LIS1, sequence variations LIS1	AD	247200	<a href="#">Click link</a>
	Nager acrofacial dysostosis	Acrofacial dysostosis resembling Treacher–Collins syndrome combined with predominantly radial limb defects	Unknown	AD	154400	

Opitz G/BBB	Hypertelorism, hypospadias, cleft lip/palate, laryngotracheoesophageal abnormalities, imperforate anus, developmental delay	MID1 gene	X-linked	300000	<a href="#">Click link</a>
Pentalogy of Cantrell	Anterior body wall defect, short or bifid sternum, diaphragmatic pericardium defect,	Unknown with some cases linked to Xq26.1	Sporadic	313850	
Renpenning (Golabi–Ito–Hall)	Mental retardation, microcephaly, short stature, and small testes	PQBP1 gene	X-linked	309500	
Smith–Lemli–Opitz	Mental retardation, failure to thrive, feeding, difficulties, premature death, microcephaly, micrognathia, ptosis, anteverted nostrils, 2/3 syndactyly of toes, broad alveolar ridges, short stature, genital anomalies; occasional, polydactyly, cleft palate, various other, visceral malformations, cataract	<i>DHCR7</i>	AR	270400	<a href="#">Click link</a>
Thrombocytopenia—absent radius (TAR)	Bilateral absent radius, (thumbs are present) ulnar hypoplasia, thumbs present, occasionally mentally retarded, squint,	200 kb deletion, chromosome 1q21.1	Unknown	274000	<a href="#">Click link</a>
Timothy	Lethal arrhythmias, syndactyly, immune deficiency, intermittent hypoglycemia, mental retardation, autism	CACNA1C	AD, de novo	601005	<a href="#">Click link</a>
Townes–Brocks	Imperforate anus, dysplastic ears, hearing loss, thumb malformations, renal impairment/ anomalies	SALL1	AD	107480	<a href="#">Click link</a>
VATER/ VACTERL	Vertebral defects (V), anal atresia (A), tracheoesophageal fistula with esophageal atresia (TE), and radial or renal dysplasia (R), cardiac malformations (C) and limb anomalies (L) Three or more of the above is suggestive of the diagnosis	Unknown	Sporadic	192350	
Yunis–Varon	Dolichocephaly, wide anterior fontanelles, sparse hair, dysmorphic, thin lips, short philtrum, micrognathia, absent thumbs, hypoplastic clavicles		AR	216340	

<sup>a</sup>Syndromes may be associated with multiple types of cardiac defects.

<sup>b</sup>Space does not permit the inclusion of every case report or occasional observation.

## Biographies

**Dr Rocio Moran, MD, FACMG**  
Assistant Professor of Pediatrics  
Cleveland Clinic Lerner College of Medicine

Rocio Moran is the Medical Director and section head of Pediatric Genetics at the Center for Personalized Genetic Healthcare, in the Genomic Medicine Institute of the Cleveland Clinic Foundation in Cleveland, Ohio. Dr Moran earned her BS from The Ohio State University in Molecular Genetics and her MD from Case Western Reserve University School of Medicine. She did her post-graduate training at the University Hospitals of Cleveland/ Rainbow Babies and Children's Hospital in Cleveland, Ohio and is boarded in Pediatrics and Medical Genetics. She joined the Cleveland Clinic Foundation in 2006. Her clinical interests include the natural history, diagnosis and management of connective tissue disorders, the evaluation of patients with birth defects, and the integration of genetics and genetic counseling into primary care and sub-specialty clinical practice.

For more information on Dr Moran, please see: [http://my.clevelandclinic.org/staff\\_directory/physician\\_name\\_search.aspx#7447](http://my.clevelandclinic.org/staff_directory/physician_name_search.aspx#7447).

**Dr Nathaniel H Robin, MD (FACMG)**  
Professor of Genetics and Pediatrics  
University of Alabama at Birmingham

Dr Robin attended Albert Einstein College of Medicine in the Bronx, New York, where he also completed a residency in pediatrics. He then proceeded to do a fellowship in Genetics at The Children's Hospital Philadelphia/University of Pennsylvania. His first faculty position was in the Department of Genetics at Case Western Reserve University School of Medicine in 1995. In 2003, Dr Robin joined the newly created Department of Genetics at the University of Alabama at Birmingham. Dr Robin is board certified in Clinical Genetics by the American Board of Medical Genetics. His clinical practice is primarily as a general medical geneticist, with expertise in pediatric genetics, syndrome identification and genetic counseling. His areas of focused interest include craniofacial disorders, and the genetics of deafness. While maintaining an active clinical practice, Dr Robin has authored one book (*Medical Genetics: Its Application to Speech, Hearing, and Craniofacial Disorders*), 15 book chapters, over a dozen invited editorials and over one hundred peer-reviewed publications. His writings cover a wide range of topics in genetics and include descriptions and studies on a variety of genetic syndromes. He has published studies that have looked at genetics testing for deafness, and on ethical issues in genetic testing, including issues of confidentiality and duty to warn at risk relatives. Dr Robin is the Medical Genetics residency program director at The University of Alabama at Birmingham. For more information on Dr Robin, please see [http://135.25.56.115/depts/MEB/SOMResearchFaculty/currentfacultydata.asp?s\\_lname=robin&s\\_keyword=&s\\_fname=nathaniel&s\\_Department\\_Name=genetics&s\\_ResearchTitle=&ID=robin](http://135.25.56.115/depts/MEB/SOMResearchFaculty/currentfacultydata.asp?s_lname=robin&s_keyword=&s_fname=nathaniel&s_Department_Name=genetics&s_ResearchTitle=&ID=robin).

© 2007, Elsevier Ltd.

### 47.1 INTRODUCTION

Cardiomyopathies are disorders of the heart muscle (myocardium) that produce characteristic changes in cardiac morphology and function, typically described as hypertrophic or dilated remodeling. Although a variety of etiologies account for compensatory forms of cardiac remodeling are recognized, inherited and de novo gene mutations are the most prevalent causes for primary cardiomyopathies. Discovery of the gene mutations that cause cardiomyopathies has advanced knowledge of the complex cellular and molecular events that propel cardiac remodeling. Despite similar clinical presentations, not all cases of cardiomyopathies that are classified as dilated or hypertrophic reflect a common underlying pathophysiology. Elucidating the different molecular mechanisms leading from genetic mutation to the clinical expression of these disorders has had profound impact on our understanding of basic myocyte biology. This knowledge is increasingly impacting opportunities for personalized approaches to disease management for cardiomyopathy patients.

### 47.2 HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) was first described centuries ago, but modern clinical descriptions appeared in the mid 1950s and over the past 20 years, the molecular genetic basis of HCM has been elucidated. HCM is defined by the presence of unexplained cardiac

hypertrophy in a nondilated ventricle (Figure 47-1). “Unexplained” indicates that left ventricular hypertrophy (LVH) develops in the absence of any systemic or cardiac condition (such as hypertension or valvular heart disease) that may impose an increased load on the heart. HCM is usually familial and inherited as an autosomal dominant trait. Genetic studies have defined HCM to be a disease of the sarcomere, caused by mutations in eight major genes that encode different components of the contractile apparatus.

Many historical descriptions of HCM reported severe morphologic manifestations of the condition, including profound hypertrophic remodeling, marked left ventricular outflow tract obstruction, and adverse clinical outcomes, most notably sudden death. However, with the contemporary widespread use of robust noninvasive imaging techniques, HCM is now recognized to be a prevalent cardiovascular disorder with highly variable manifestations. Clinical presentation can occur throughout life, including late in adulthood. Hypertrophy is usually modest and typically involves the interventricular septum. Significant outflow tract obstruction occurs in ~25% of patients, although a provokable gradient may be detected in larger proportion of patients by administering medications or through maneuvers that impact preload or cardiac contractility. Importantly, for of the most patients, life expectancy is normal and symptoms do not necessitate major interventions.

**FIGURE 47-1** A comparison of normal cardiac anatomy and cardiac remodeling. A. Normal myocardium with left ventricular (LV) wall thickness  $\leq 11$  mm and normal LV volume. B. Hypertrophic cardiomyopathy cause increased LV wall thickness without cavity dilation. C. DCM causes enlargement of LV and occasionally right, ventricular cavity size. (Reproduced with permission from Ahmad, F.; Seidman, J. G.; Seidman, C. E. *The Genetic Basis for Cardiac Remodeling*. Annu. Rev. Genomics Hum. Genet. **2005**, 6,185–216.)

### 47.2.1 Prevalence

In a general population of young adults, the prevalence of unexplained LVH, the prototypic clinical feature of HCM, is 1 in 500 (1). Among a community-based cohort, the Framingham Heart Study, ~3% of participants have unexplained LVH. While the prevalence of unexplained LVH that is familial is unknown, these epidemiologic data support the claim that HCM is the most common genetic cardiovascular disorder (2,3). The prevalence of HCM in the general population may explain why this diagnosis accounts for most non-violent sudden deaths in individuals under the age of 35 and is the most common cause of sudden death in athletes, occurring in one-third of these events (4).

A small number of genetic epidemiologic studies have been performed to investigate the prevalence of sarcomere mutations in different populations. Direct DNA sequencing of six sarcomere genes (MYH7, TNNT2, TNNI3, TPM1, ACTC1, and MYBPC3) was performed on a cohort of 389 unrelated probands referred for management of HCM to a single center. Of these, 147/389 (38%) were found to have sarcomere mutations, most commonly involving MYH7 and MYBPC3 (87% of mutation positive individuals) (5–8). In contrast, a separate study that analyzed eight sarcomere protein genes (including MYL3 and MYL2) in subjects with familial HCM, identified sarcomere gene mutations in 75% of cases (9), with the majority of mutations occurring in MYH7 and MYBPC3. Together these studies indicate that a positive family history is a strong predictor of positive genetic testing.

Genetic analyses have begun to address whether sarcomere protein genes also contribute to LVH that occurs in the context of other common cardiovascular disorders. Analyses of 50 participants in the Framingham Heart Study with LVH that occurred in the context of hypertension and atherosclerosis, a rare sarcomere protein gene mutation was identified 16%, while only normal gene sequences were observed in Framingham Heart Study participants with no evidence of LVH (10).

### 47.2.2 Pathology

HCM causes several patterns of hypertrophy, including asymmetric involvement of the interventricular septum (Figure 47-1), concentric hypertrophy and apical hypertrophy (11). There is significant variation in both the location and extent of LVH in affected individuals and no correlation between genetic etiology and cardiac morphology (12). The histopathologic hallmarks of HCM are myocyte enlargement, myocyte disarray and increased amounts of myocardial fibrosis (Figure 47-2). Although small amounts of myocyte disarray may be seen in other forms of cardiac disease, the higher degree of disarray present in HCM is distinctive. The distribution of disarray may be patchy and typically affects the deeper myocardial layers; therefore, catheter-based endomyocardial biopsy is often nondiagnostic. Small vessel disease with thickening of the walls of intramural arteries is also seen in HCM and may be correlated with clinical ischemia.

### 47.2.3 Phenotype and Natural History

**47.2.3.1 Phenotype.** The clinical spectrum of HCM is extremely diverse. Whereas some individuals experience only minor symptoms and are diagnosed incidentally or in the course of family screening, others may develop refractory symptoms of pulmonary congestion or end-stage heart failure requiring cardiac transplantation. In a small subset of patients, sudden cardiac death is the presenting event (13,14–16). Shortness of breath or dyspnea, particularly on exertion, is the most common symptom of HCM, occurring in ~90% of patients. In case that diastolic function is severely impaired, shortness of breath can happen with the absence of left ventricular outflow tract obstruction or valvular dysfunction. Other common clinical manifestations include exertional chest pain (~30% of patients), palpitations, atrial fibrillation (~25%) with associated risk of stroke, orthostatic lightheadedness, presyncope (>50%) and syncope (15–25%), orthopnea/paroxysmal nocturnal dyspnea, and fatigue (16,17).

**FIGURE 47-2** Normal and pathologic myocardial histology. A and C. Normal cardiac histology is characterized by orderly myocyte structure and minimal interstitial fibrosis. B. Hypertrophic cardiomyopathy is characterized by marked myocyte disarray, hypertrophy and interstitial fibrosis. D. Compared with normal tissue, increased interstitial fibrosis (blue) is evident by the Masson trichrome stain in both HCM. (*Reproduced with permission from Ahmad, F.; Seidman, J. G.; Seidman, C. E. The Genetic Basis for Cardiac Remodeling. Annu. Rev. Genomics Hum. Genet. 2005, 6, 185–216.*)

Symptoms and the incidence of atrial fibrillation typically increase with disease duration. In patients with outflow tract obstruction, cold weather leading to reflex vasoconstriction can lessen symptoms due to increased arterial pressure and subsequently decreased outflow obstruction. This finding is opposite in patients with coronary artery disease (11). Although there is limited correlation between morphologic findings and clinical manifestations, more recent studies suggest that the presence of significant outflow tract obstruction  $>50$  mmHg should be considered as an important determinant of adverse outcomes in HCM (18).

Typical findings on physical examination include a prominent left ventricular apical impulse or lift, a fourth heart sound (S<sub>4</sub>), and a brisk, occasionally bifid carotid upstroke. If obstruction is present, there may be a harsh crescendo–decrescendo systolic murmur that is typically the best heard at the lower left sternal border and apex, radiating to the axilla and base, but usually not to the neck as classically audible in valvular aortic stenosis. A separate murmur of mitral regurgitation may also be present, related either to concomitant intrinsic structural abnormalities of the mitral valve or as a consequence of systolic anterior motion (SAM) of the mitral apparatus if obstructive physiology is present. Maneuvers that alter preload and afterload are recommended for discriminating of HCM and valvular aortic stenosis. Preload or afterload reduction from these maneuvers enhances the dynamic gradient and accentuates the intensity of systolic murmur. Conversely, increased preload and afterload in response to maneuvers decrease murmur intensity. Although Valsava maneuver, leg-raising,

amyl nitrite inhalation can change murmur intensity, the classic maneuver that has been recommended is standing–squatting–standing. From standing to squatting, the murmur decreases in intensity due to increased preload and afterload. While the patient is standing from squatting position, the loudness of murmur is then accentuated as a result of rapidly decreased afterload.

The traditional description of HCM relies on the finding of unexplained LVH, usually via electrocardiography (EKG) or echocardiography. Magnetic resonance imaging (MRI) can complement echocardiography when findings are inconclusive. LV wall thickness in excess of two standard deviations above normal or  $>13$  mm in the adult population are the widely accepted echocardiographic criteria for establishing the diagnosis of HCM. Although considered diagnostic of the condition, LVH is not uniformly present in all individuals with sarcomere gene mutations, particularly early in life due to age-dependent penetrance (19,20). Furthermore, the severity of symptoms associated with HCM is not directly related to the magnitude of hypertrophy (13,15). Although a pattern of asymmetric septal hypertrophy is most common, any pattern of LVH may be seen, including isolated apical hypertrophy, concentric hypertrophy or asymmetric hypertrophy involving other myocardial segments (21).

Left ventricular systolic function is typically preserved in HCM and ejection fraction is often increased (22). However, abnormal diastolic function has been well documented and may largely account for symptoms of pulmonary congestion and exercise intolerance (22–24).

Electrocardiographic changes are present in ~90% of affected individuals and may be detected prior to the development of echocardiographic manifestations. However, given the high incidence of nonspecific EKG changes in the general population, EKG findings do not have a higher sensitivity or specificity for diagnosing HCM than echocardiography. Prototypical EKG findings include pathologic Q waves in at least two leads, T wave inversion in at least two leads, and voltage criteria for LVH (25,26). The occurrence of other EKG abnormalities such as pre-excitation and AV block may indicate the presence of other gene mutations that clinically mimic HCM (see below).

HCM patients may have an abnormal fall in blood pressure in response to exercise, possibly related to abnormal vasomotor tone or inability to augment stroke volume in response to increased demand. This finding may indicate a worse prognosis with a higher risk for sudden death (18,27,28).

**47.2.3.2 Natural History.** The natural history of HCM varies, even between family members who have inherited the same causal mutation. Although it is not uncommon for HCM to present in infancy or early childhood; development of LVH typically occurs in adolescence in conjunction with the pubertal growth spurt. The age of onset of hypertrophy may be determined to some extent by the specific nature of the underlying gene defect (20,29). Disease caused by mutations in the  $\beta$ -myosin heavy chain (MYH7) gene is typically associated with clinically obvious disease and nearly uniform development of LVH by the second decade of life. In contrast, clinically evident hypertrophy may not be present until the fourth or fifth decade of life in disease caused by mutations that introduce a premature truncation in the cardiac myosin binding protein C (MYBPC3) gene. MYBPC mutations have also been associated with elderly onset HCM (20). Recent studies indicate that mutation-positive HCM patients have a higher degree of phenotypic severity than HCM patients with a negative genetic test, suggesting that positive genetic result is associated with adverse outcome in HCM patients (8,30).

Estimates of annual mortality in HCM are imprecisely defined. Evaluation of populations drawn from specialized referral centers suggests a significant annual mortality rate of 4–6%. In contrast, community-based studies, which may be less subject to selection bias, demonstrate a more benign course with a projected annual mortality rate of 1 to 2% (17). HCM causes premature morbidity and mortality by sudden cardiac death (accounting for approximately half of HCM-related deaths), progressive heart failure, atrial fibrillation associated with an increased risk of thromboembolism and stroke, and heart failure. Sudden death is the most feared complication of HCM, and accurate estimation of an individual's risk for sudden death is a considerable clinical challenge. The annual risk for sudden death in the overall HCM population varies from 1 to 5% with ~10–20%

of patients at the highest risk (13,14,31). Heart failure may develop in patients with HCM and is associated with an annual mortality of 0.5%. Less than 10–20% of the patients progress to the “burnt-out” phase of HCM, marked by worsening symptomatic heart failure, left ventricular systolic dysfunction, progressive LV wall thinning, and chamber dilatation (13–15). These patients may ultimately require cardiac transplantation for end-stage heart failure.

## 47.2.4 Genetics

HCM is inherited as a Mendelian autosomal dominant trait. Linkage analysis of large kindreds with HCM initially identified several disease loci on chromosomes 1 (32), 11 (33), 14 (34), and 15 (35). Positional cloning and candidate gene analysis identified definitive pathogenic mutations in genes that encode different elements of the contractile apparatus, including cardiac  $\beta$ -myosin heavy chain (MYH7), cardiac troponin T (TNNT2) and I (TNNI3), cardiac myosin binding protein C (MYBPC3),  $\alpha$ -tropomyosin (TPM1), actin (ACTC1), and the essential (MYL3) and regulatory (MYL2) myosin light chains (Table 47-1; reviewed in (36,37). Also see *Cardiogenomics* website. Thus, genetic studies established the paradigm of HCM as a disease of the sarcomere (Figure 47-3)).

The sarcomere is the functional unit of contraction of the myocyte. Proteins are organized into thick (myosin heavy and light chains) and thin (actin, the troponin complex, and  $\alpha$ -tropomyosin) filaments that interdigitate during muscle fiber shortening and lengthening. The detachment and attachment of actin and the myosin head drive contraction and relaxation at the molecular level. The hydrolysis of adenosine triphosphate (ATP) provides fuel for this motor and carefully orchestrated fluxes in intracellular  $\text{Ca}^{2+}$  concentration coordinate thick- and thin-filament interaction (reviewed in References (38,39)). Membrane depolarization by the action potential elicits calcium influx through cell membrane L-type calcium channels. Ryanodine receptors (RyR2) on the sarcoplasmic reticulum (SR) are then activated to trigger calcium-induced calcium release. The resultant rise in intracellular  $\text{Ca}^{2+}$  concentration leads to calcium binding of troponin C and causes conformational changes in the troponin complex, releasing troponin I inhibition of actin and allowing actin-myosin cross-bridge formation. Myosin then hydrolyzes ATP and undergoes conformational changes that allow the myosin head to be propelled against the thin filament. Activation of the sarcoplasmic/endoplasmic  $\text{Ca}^{2+}$ -ATPase membrane pump, SERCA, causes sequestration of cytosolic  $\text{Ca}^{2+}$  back into the SR. The myosin head detaches from actin, troponin I inhibition of actomyosin interaction is reestablished, and myocyte relaxation ensues (Figure 47-4).

To date, more than 900 individual mutations have been identified in genes that encode different components of the contractile apparatus (40,41), summarized in

**TABLE 47-1 Gene Mutations That Cause Unexplained Left Ventricular Hypertrophy**

	Gene	Designation	Chromosome	Frequency	Number of Mutations	Phenotypic Correlation
HCM-sarcomere proteins	$\beta$ -Myosin heavy chain	MYH7	14q1	~35%	>200	Typically obvious disease with significant LVH; several severe phenotypes (end-stage heart failure and sudden death)
	Cardiac myosin binding protein C	MYBPC3	11q1	~40%	>150	Typically more mild disease but severe phenotypes have been described; early-onset HCM
	Cardiac troponin T	cTnT	1q3	~8%	>30	Typically mild LVH but increased associated with sudden death
	Cardiac troponin I	cTnI	19p1	~10%	27	
	$\alpha$ -Tropomyosin	TPM1	15q2	~5%	11	
	Myosin essential light chain	MYL3	3p	Rare	5	Skeletal myopathy
	Myosin regulatory light chain	MYL2	12q	~2%	10	Skeletal myopathy
Inherited LVH	Actin	ACTC1	11q	Rare	7	
	$\gamma$ 2-Subunit AMP	PRKAG2	7q3	?	4	Glucose metabolism; pre-excitation and conduction disease; CPMVT
	Linked lysosome associated membrane protein	LAMP2	X	?	6	
	Muscle LIM protein	CRP3	11p	?	3

**FIGURE 47-3** Mutations in sarcomere protein genes are the genetic etiology of hypertrophic cardiomyopathy as well as some forms of DCM. (Modified and reproduced with permission from Spirito, P.; Seidman, C. E.; McKenna, W. J., et al. *The Management of Hypertrophic Cardiomyopathy*. N. Engl. J. Med. **1997**, *336*, 775–785.)

**FIGURE 47-4** Normal intracellular  $\text{Ca}^{2+}$  cycling (top) is altered in HCM (bottom). A. Electrical impulses generated by the cardiac action potential trigger the influx of  $\text{Ca}^{2+}$  via L-type calcium channels, causing a larger calcium-induced calcium release (CICR) in which  $\text{Ca}^{2+}$  from SR stores is released into the cytoplasm via ryanodine receptors (RyR2) on the SR membrane.  $\text{Ca}^{2+}$  binds to the troponin complex of the sarcomere, releasing inhibition of troponin I, allowing actomyosin interaction and the generation of the power stroke.  $\text{Ca}^{2+}$  returns to the SR via reuptake by the sarcoplasmic/endoplasmic  $\text{Ca}^{2+}$ -ATPase pump (SERCA), which is regulated by phospholamban (PLB). (Adapted with permission from Semsarian, C.; Ahmad, I.; Giewat, M., et al. 2002) B. Sarcomere mutations (asterisk) alter  $\text{Ca}^{2+}$  cycling, so that SR is diminished, resulting in depletion of SR calsequestrin (CSQ), and RyR2. (Adapted with permission from Semsarian, C.; Ahmad, I.; Giewat, M., et al. *The L-type Calcium Channel Inhibitor Diltiazem Prevents Cardiomyopathy in a Mouse Model*. J. Clin. Invest. **2002**, 109, 1013, with permission of The American Society for Clinical Investigation.)

**Table 47-1 (36,42–44).** A variety of types of mutations have been described, including missense, nonsense, short insertions and deletions, and alteration of splice donor or acceptor sites. De novo or sporadic mutations are also well described, although the relative prevalence of sporadic mutations versus familial disease remains unclear. The vast majority of mutations tend to be “private” or unique from family to family with rare reappearances in unrelated kindreds and haplotype analyses of unrelated patients who carry a shared HCM mutation often demonstrate that these genetic defects arose independently (45).

In contrast, several founding HCM mutations have been identified in some populations, as evidenced by shared haplotype architecture amongst mutation carriers. Some of these have been identified in homogenous populations with geographic or societal isolation, including subsets of populations in India (46), Finland (47), The Netherlands (48), Japan (49), South Africa (50), and in the United States (45). The maintenance of founding mutations in these populations is likely to reflect neutral evolutionary pressure due to benign or late-onset HCM manifestations and adverse outcomes that are delayed until after the reproductive age (37). Given a markedly increased human longevity, the effect of these genetic defects has also become even more apparent, as these contribute to an increased risk for heart failure in mutation carriers (46).

Mutations in cardiac  $\beta$ -myosin heavy chain, cardiac myosin binding protein C, and cardiac troponin T and I account for ~80–90% of described cases of HCM (43). Clinical correlates associated with mutations in different HCM genes have emerged (51) and are broadly outlined

in **Table 47-1**; however, numerous exceptions to these themes have been documented (52). However, a discrete number of mutations identified in some families are associated with higher incidence of adverse events, including sudden death and/or heart failure, in mutations carriers. With the exception of these, genotype in isolation is often insufficiently predictive of outcome, and integration of existing information associated with a particular mutation with clinical risk assessment is appropriate. Further identification of causal mutations and more accurate definition of genotype–phenotype correlations remain a work in progress, but the wide genetic and clinical spectrum of HCM make this a challenging task. As our ability to more precisely and sensitively assess the full spectrum of the HCM phenotype improves, more accurate associations will emerge. It remains unclear why some sarcomere mutations cause more severe disease than others and why individuals with the same mutation have a wide range of clinical features. Description of wider genetic and environmental factors that shape the expression of the underlying mutation is an active area of investigation.

#### 47.2.4.1 Cardiac $\beta$ -Myosin Heavy Chain (MYH7).

Myosin heavy chains account for ~1% of total myocyte protein. They are large molecules of >200,000 kDa, organized into two functional domains: an amino terminal globular head that interacts with actin and a carboxyl terminal rod (53,54). Force is transduced via a hinge region between these two domains. There are two cardiac-specific myosin heavy chain isoforms:  $\alpha$ -cardiac MHC (MYH6) and  $\beta$ -cardiac MHC (MYH7). Both genes are encoded in tandem on chromosome 14. The  $\alpha$ -isoform predominates

in fetal life and in the adult atria; the  $\beta$ -isoform predominates in the adult, accounting for more than 70% of total ventricular myosin (55). The majority of HCM-causing mutations is of the missense variety and clustered within the globular head. The genetic basis of HCM was first described as a missense mutation in this gene resulting in the substitution of glutamine for arginine at residue 403 (Arg403Gln) (56).

Hundreds of different MYH7 missense mutations have been reported in both familial and sporadic disease. Overall MYH7 mutations account for ~35% of cases of HCM (43,44,57). The phenotypic expression of these mutations is usually obvious with significant degrees of LVH apparent by late adolescence. However, recent studies indicate that 33.3% of familial childhood-onset HCM and 17.6% of sporadic childhood-onset HCM carry MYH7 mutations (9). Another independent study shows that a total of 16.7% of HCM patients with sarcomeric mutations were diagnosed even before 1 year of age. More than half of these pediatric patients also have family history of HCM (58). These findings could be attributable to background genotypes, lifestyle and environmental factors, presumably contributing to the clinical onset of HCM with MYH7 mutations or other gene mutations. Although heterogeneous, the clinical course of certain MYH7 mutations has been quite severe, associated with an increased risk of sudden death or development of end-stage heart failure. The precise determinants of the relationship between prognosis and underlying gene mutation are likely multifactorial and currently incompletely understood. Mutations that result in a change in the charge of the substituted amino acid may result in more severe disease, presumably due to more dramatic effects on protein structure and function.

**47.2.4.2 Cardiac Myosin Binding Protein C (MYBPC3).** The cardiac myosin binding protein C gene (MYBPC3) contains 37 exons spanning 24kb of chromosome 11 and encoding a 1274-amino-acid (137kDa) protein. Cardiac myosin binding protein C is arrayed into strips that provide structural support to the sarcomere by binding myosin heavy chain and titin (59,60). Functionally, cardiac myosin binding protein C protein may provide structural integrity to the sarcomere as well as modulate myosin ATPase activity and cardiac contractility in response to adrenergic stimulation. HCM mutations in MYBPC3 include missense, splice site, and deletion/insertion mutations and account for ~45% of cases of HCM (9,43,44). In a significant subset of individuals with MYBPC3 mutations, the development of clinically apparent LVH is delayed until age 50 years or above (20,29). MYBPC3 mutations have also been identified in 20% of a cohort of individuals with elderly-onset HCM, which is distinguished by late-onset hypertrophy and absence of family history (20). Similar to MYH7 mutations, MYBPC3 mutations have been identified in 21.2% of familial childhood-onset HCM and 25.5% of sporadic childhood-onset HCM (9). Most of childhood-onset

mutations are missense (76%) while 60% of previously reported mutations in adults encode truncation. This observation implies higher functional consequences of missense mutations than those of truncation mutations.

Several founding mutations have been identified in MYBPC3 gene, most of which cause truncated amino acid sequences. Amongst south Asians, a 25-bp deletion in intron 32 in MYBPC3 accounts for HCM in 4% of Indian subcontinental population (46). This common variant is associated with disorganized cardiac myocyte architecture in vitro and a sevenfold increased risk of chronic heart failure. This data suggests that analysis of HCM-causing genes would emerge as a promising strategy for identifying persons at high risk for cardiac remodeling and heart failure (61).

**47.2.4.3 Cardiac Troponin T (TNNT2).** Cardiac troponin T links the troponin complex to  $\alpha$ -tropomyosin and thus plays a central role in the regulation of contractile function. The cardiac troponin T gene (TNNT2) spans 17kb of DNA on chromosome 1 and encodes a 288-amino-acid peptide (36–39kDa). Several distinct isoforms are expressed in cardiac tissue via alternative splicing of 16 exons (62). Approximately 10% of HCM is thought to be attributable to TNNT2 mutations. Historically, the clinical phenotype resulting from TNNT2 mutations has been characterized by modest or clinically unapparent amounts of LVH but increased risk of sudden death. However, this classic description is based on information from a highly selected, referral-based population, and “benign” TNNT2 mutations have also been reported (63,64).

**47.2.4.4  $\alpha$ -Cardiac Actin (ACTC1).** This 375-amino-acid protein (41kDa) is encoded by the cardiac actin gene (ACTC1) and organized into six exons on chromosome 15 (65). Mutations in actin are typically located in proximity to the putative myosin binding site and are a rare cause of HCM (57,66). Actin mutations have also been identified as a rare cause of familial dilated cardiomyopathy (DCM) (~1%) (67).

**47.2.4.5  $\alpha$ -Tropomyosin (TPM1).** The  $\alpha$ -tropomyosin gene (TPM1) is organized into 15 exons on chromosome 15 (68) and encodes a 284-amino-acid protein expressed in both fast skeletal and cardiac muscle (69).  $\alpha$ -tropomyosin forms a complex with troponin T that regulates actin-myosin interaction in response to intracellular  $\text{Ca}^{2+}$  concentration. Calcium binding to troponin C causes conformational changes in troponins I and T that ultimately allow actin-myosin cross-bridge formation. Mutations in TPM1 are thought to account for a small proportion (~5%) of familial and sporadic HCM (70,71), including a potential founding mutation that arose in the Finnish population (72).

Although  $\alpha$ -tropomyosin is expressed in both cardiac and skeletal muscle, the clinical expression of TPM1 mutations is dominated by HCM, rather than skeletal myopathy. The cardiac specificity of phenotype may be due to the fact that the identified mutations alter the

portions of the  $\alpha$ -tropomyosin molecule that interact with the cardiac-specific isoform of troponin T. Alterations in  $\text{Ca}^{2+}$  sensitivity may also play a role in the tissue-specificity of TPM1 mutations (73).

**47.2.4.6 Cardiac Troponin I (TNNI3).** Cardiac troponin I is the inhibitory subunit of the troponin complex, acting to inhibit actin-myosin interaction. When  $\text{Ca}^{2+}$  binds to troponin C, conformational changes occur in troponin I that release the inhibition of troponin T and  $\alpha$ -tropomyosin, allowing actomyosin cross-bridge formation to occur. The cardiac-specific isoform of troponin I (TNNI3) spans eight exons on chromosome 19 and encodes a 210-amino-acid (27–31 kDa) protein (74). Direct DNA sequence analysis of TNNI3 in patients with HCM suggests that mutations in this gene account for ~10% of disease. Detailed survival analyses have not been performed.

**47.2.4.7 Myosin Light Chains.** The regulatory (MYL2, chromosome 12) and essential (MYL3, chromosome 19) myosin light chains belong to the EF-hand superfamily of proteins with a helix–loop–helix motif (75). They may be involved in determining the speed and force of actomyosin sliding by interacting with the head-rod junction of myosin molecules (76,77). Mutations in myosin light chains are rarely reported genetic etiologies of HCM, accounting for 1–3% of disease (78).

**47.2.4.8 Putative HCM Genes.** Despite substantially rare occurrences in only a small number of isolated probands, mutations in other genes, including  $\alpha$ -actinin (79),  $\alpha$ -MHC (20), cardiac ankyrin repeat protein (ANKRD1; Ref. (80)), cardiac troponin C (TNNC1; Ref. (81)), metavinculin (VCL) and MLP (CSRP3; Ref. (82)), myozenin 2 (MYOZ2; Ref. (83)), phospholamban (PLN; Ref. (84)), telethonin (TCAP Ref. (85)), titin (TTN; Ref. (86)), and vinculin (VCL; Ref. (87)) have been reported in association with HCM. Clinical significances of these genes have not yet been definitely determined due to a paucity of strong evidence that these are definitive HCM genes. Most of these genes are not included in clinical genetic testing for HCM.

## 47.2.5 Animal Models of HCM

Mutations in sarcomere proteins may alter actin-myosin interaction, intracellular calcium cycling, force generation or the transmission of force. However, the heterogeneity of HCM in the human population has challenged the dissection of the precise molecular mechanisms that lead from inherited gene defect to clinical phenotype.

To evaluate the consequences of specific mutations experimental cell and in vivo models of HCM have been developed. Genetically modified animals have been developed incorporating different human mutations in MYH7, MYBPC3, and TNNT, and TNNI3. Rodents carrying these gene mutations develop a phenotype that recapitulates human HCM, including age-dependent myocardial hypertrophy, fibrosis, and myocyte disarray. Interrogation of the biophysical properties of sarcomeres

with particular mutations with myocardial contractility, myocyte biochemistry and transcriptional responses has helped to clarify the molecular events associated with specific HCM mutations.

An HCM model (denoted as  $\alpha$ -MHC<sup>403/+</sup>) that expresses the human myosin heavy chain mutation, Arg403Gln (88) has been extensively studied. The cardiac phenotype of  $\alpha$ -MHC<sup>403/+</sup> mice closely mirrors human HCM histopathology. Although general life expectancy is not significantly altered, heterozygous mice demonstrate increased arrhythmogenicity and risk for exercise-induced sudden death as compared with their wild-type littermates (89). Enhanced systolic contractile performance (dominant-activating effect) was identified by examining single mutant myosin molecules from  $\alpha$ -MHC<sup>403/+</sup> myocytes as well as intact heart preparations (90–92). Diastolic function has been shown to be significantly impaired even prior to the development of hypertrophy (93).

Why sarcomere protein mutations in cardiac myocytes that enhance biophysical properties lead to cardiac hypertrophy became an important mechanistic question. Biochemical studies highlighted the crucial role of intracellular  $\text{Ca}^{2+}$  handling plays in linking alterations of muscle contraction to myocyte hypertrophy.  $\alpha$ -MHC<sup>403/+</sup> myocytes have diminished SR release of calcium in response to caffeine and decreased levels of calcium binding proteins calsequestrin, ryanidine receptor, triadin, and junctin (94). These biochemical alterations may worsen cardiac diastolic dysfunction in HCM. Abnormal calcium signaling has been demonstrated in other mouse models harboring a human mutation in troponin T (95) and regulatory myosin light chains (96) and has been proposed to be a remarkable characteristic of other cardiomyopathies (97,98).

The biochemical defects identified in HCM models has raised the possibility that diminishing calcium signals might be beneficial in HCM. To test this, the L-type calcium channel blocker, diltiazem was administered to young  $\alpha$ -MHC<sup>403/+</sup> mice (99) prior to the development of histologic or morphologic abnormalities (prehypertrophic phase: age 6–8 weeks). Diltiazem treatment was associated with a decreased degree of fibrosis, and hypertrophy, both at the gross and histologic levels. Aberrant myocyte biochemistry was also improved with normalization of levels of calcium binding proteins (Figure 47-5) (94,100). One consequence of the Arg-403Gln mutation may be abnormal sequestration of calcium by the mutant sarcomere with ultimate depletion of SR  $\text{Ca}^{2+}$  levels. Diltiazem may serve to blunt this effect by restoring more appropriate calcium cycling between the SR and the cytoplasm and thereby interrupting the signals leading to hypertrophic remodeling. Fundamental dysregulation of calcium handling caused by myosin mutations may in part mediate the hypertrophic response of the myocyte (Figure 47-4).

Calcium cycling abnormalities may enhance the probability for after depolarization in cardiac myocytes, a

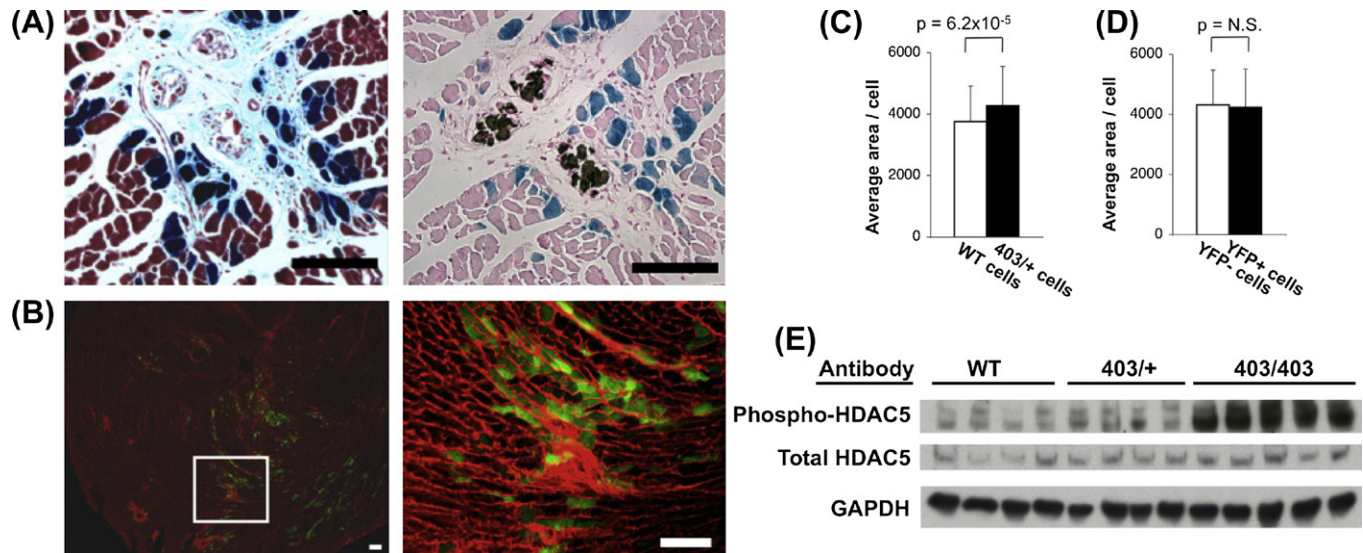

**FIGURE 47-5** Normalization of abnormal  $\text{Ca}^{2+}$  improves histopathology in a mouse model of HCM. Left panel. Histopathology of diltiazem-treated wild-type and  $\alpha\text{-MHC}^{403/+}$  mice as compared with untreated mice. Whole heart sections (top; magnification =  $2.5\times$ ) stained with Masson trichrome reveals fibrosis (blue staining) in untreated HCM mice. Histology (bottom; magnification =  $100\times$ ) shows a reduction in myocyte hypertrophy, disarray, and fibrosis in diltiazem-treated animals compared with untreated animals. Right panel. Cardiac myocyte  $\text{Ca}^{2+}$ -related protein expression is normalized by diltiazem treatment. Western blot analysis of calsequestrin (CSQ), ryanodine receptor (RyR2), triadin, and junctin shows a reduction in the amount of protein expression in untreated  $\alpha\text{-MHC}^{403/+}$  mice. Diltiazem treatment for 8 days (CSQ) or 30 weeks (triadin, junctin, RyR2, CSQ) leads to normalization of the expression levels of these proteins. Coomassie staining is shown to indicate sample loading in each lane. (Adapted from Semsarian, C., Ahmad, I., Giewat, M., et al. *The L-type Calcium Channel Inhibitor Diltiazem Prevents Cardiomyopathy in a Mouse Model*. *J. Clin. Invest.* **2002**, 109, 1013, with permission of The American Society for Clinical Investigation.)

cellular substrate for cardiac arrhythmias, a rampant complication in HCM (101). Electrophysiologic studies in  $\text{MHC}^{403/+}$  mice showed more ventricular arrhythmias than in mice with low-risk mutations in the myosin binding protein C (102,103).  $\text{MHC}^{403/+}$  mice have also been used to assess the correlation between HCM histopathology and arrhythmic events. In human HCM, myocardial fibrosis has been recognized in post-mortem hearts from HCM patients who succumbed to SCD (104) and myocardial fibrosis has been proposed to be a significant contributor to life-threatening arrhythmias (105,106). However, analyses of arrhythmia susceptibility in  $\alpha\text{-MHC}^{403/+}$  mice in the context of myocardial fibrosis, hypertrophy and myocyte disarray demonstrated a significant correlation only between inducible ventricular arrhythmias and the degree of hypertrophy (107). Consistent with these experimental data, substantial LVH (LV wall thickness  $\geq 30$  mm) is established risk factor for sudden death in human patients (108). Given these findings, the strategies that prevent hypertrophy in HCM would potentially reduce the risk for arrhythmia development and sudden cardiac death. Alteration of biophysical properties and intracellular  $\text{Ca}^{2+}$  in HCM myocytes as well as higher energy demands impose great stress on cardiac myocytes. Molecular studies in the  $\alpha\text{-MHC}^{403/+}$  mouse model also indicate that fetal cardiac genes typically repressed following embryonic development

re-expressed with myocyte stress (109), a finding similar to the studies in human HCM hearts (110). Recent investigations have also uncovered a relationship between the early onset of calcium cycling defect in stressed myocytes and the premature myocyte demise and myocardial scarring (interstitial matrix expansion and focal replacement fibrosis) in HCM mouse models (111). The myocyte enhancer factor-2 (Mef2) family of transcription factors is activated in several myocardial pathologies that are marked by cardiac hypertrophy and myocardial fibrosis (112) and Mef2 expression identifies stressed myocytes. Mef2 activity has been assessed in  $\alpha\text{-MHC}^{403/+}$  mice, using a Mef2-LacZ ( $\beta$ -galactosidase) transgene. Mef2 activity in HCM hearts was strikingly inhomogeneous and closely associated with foci of myocyte necrosis and scarring (Figure 47-6). In homozygous mutant ( $\alpha\text{-MHC}^{403/403}$ ) mice that have marked and relentless pathologic remodeling until death at day 10, Mef2 activation was substantially accentuated and evident shortly before rampant myocyte demise, implicating Mef2 activation in HCM as a molecular marker of stressed myocytes that are destined to die (111). Abnormal calcium signaling can lead to Mef2 activation via calcium/calmodulin dependent protein kinase II (CaMKII) phosphorylation (113,114), a pathway that may link aberrant calcium signaling to premature myocyte death and focal myocardial scarring in HCM hearts.

**FIGURE 47-6** Mef2 activation in HCM myocytes. A. Colocalization of Mef2-dependent reporter activity with fibrosis (left, Gomori trichrome staining) and necrosis (right, von Kossa staining) in 30-week-old  $\alpha\text{MHC}403/+/\text{Mef2-LacZ}$  hearts. B.  $\beta\text{MHC}$  re-expression (green, identified by YFP) occurred in regions of myocardial scars (red, identified by WGA) in 30-week-old  $\alpha\text{MHC}403/+/\text{Mef2-LacZ}/\beta\text{MHC-YFP}$  hearts. Right shows magnified view of inset. C. Cross-sectional areas of myocytes from 30-week-old WT/ $\text{Mef2-LacZ}/\beta\text{MHC-YFP}$  hearts (WT cells; open bar) and  $\alpha\text{MHC}403/+/\text{Mef2-LacZ}/\beta\text{MHC-YFP}$  hearts (403/+ cells; black bars) irrespective of their fluorescence. D. Cross-sectional areas of the 403/+ cells grouped according to their YFP fluorescence (YFP- and YFP+, respectively). E. Increased phosphorylation of HDAC5 and Mef2-dependent reporter activity in  $\alpha\text{MHC}403/403$  hearts. Western blot analyses of protein lysates from 6-day-old WT,  $\alpha\text{MHC}403/+ (403/+)$ , and  $\alpha\text{MHC}403/403 (403/403)$  hearts, reacted with antibodies specific Phospho-HDAC5, total HDAC5, and GAPDH. (Adapted from Konno, T.; Chen, D.; Wang, L., et al. *Heterogeneous Myocyte Enhancer Factor-2 (Mef2) Activation in Myocytes Predicts Focal Scarring in Hypertrophic Cardiomyopathy*. PNAS **2010**, 107, 18097–18102.)

HCM mice have also been studied to define the early transcriptional changes that occur in response to a sarcomere gene mutation (109,115). All expressed RNAs in mutant myocyte and non-myocyte cells from the hearts of young prehypertrophic mice were compared with RNAs found in myocytes and non-myocytes from wild-type mice. These experiments revealed a striking increase in the expression of pro-fibrotic molecules within the transforming growth factor (Tgf) signaling pathway (including Tgf- $\beta$ 1, Tgf- $\beta$ 2, periostin and connective tissue growth factor) and cell-cycle proteins in non-myocyte cells of prehypertrophic hearts. BrdU labeling and Ki617 immunostaining confirmed transcriptional profiling data and revealed increased proliferation of non-myocytes.

To assess whether silencing of these profibrotic molecules could prevent the emergence of HCM pathology, anti-Tgf- $\beta$  neutralizing antibody was administered to young prehypertrophic mutant mice, a treatment that markedly diminished the emergence of myocardial fibrosis and hypertrophy (Figure 47-7) (115). To extend these studies, losartan, an angiotensin II (type 1) receptor antagonist was also used to inhibit Tgf- $\beta$  pathway signals. Similar to the neutral antibodies, chronic administration of losartan to prehypertrophic mutant mice prevented the emergence of LV hypertrophy and HCM pathologic features (Figure 47-7). Taken together, these data define Tgf- $\beta$  signaling as a pivotal mechanism for myocardial fibrosis development and a potentially important contributor to diastolic dysfunction and heart failure (Figure 47-8). Preemptive pharmacologic antagonism of Tgf- $\beta$  signals

warrants clinical study in asymptomatic patients with sarcomere gene mutations.

In addition to the  $\alpha\text{-MHC}$  mouse model, a variety of other genetically modified mice, rats, and rabbits have been developed, incorporating mutations in  $\beta\text{-myosin}$  heavy chain, cMyBPC,  $\alpha\text{-tropomyosin}$ , and cardiac troponin T (93,116–120). These models typically show myocyte disarray, variable degrees of hypertrophy, systolic and diastolic dysfunction. The  $\beta\text{-MHC}^{403/+}$  transgenic rabbit model (117) is an attractive model, as the  $\beta$ -isoform of MHC is predominant in rabbit and adult human hearts, whereas the  $\alpha$ -isoform predominates in mice and rats. These rabbits show significant hypertrophy, fibrosis, diastolic dysfunction and an increased risk of sudden death (117). As with the  $\alpha\text{-MHC}^{403/+}$  mouse model, impaired myocardial relaxation develops in advance of hypertrophy (121). This finding has recently been replicated and extended to human patients with HCM (122).

Pharmacologic studies have also been performed to target fibrosis pathways rather than intracellular calcium handling and to reverse myocardial fibrosis in some other animal models of HCM. For examples, angiotensin II receptor type 1 blockade was associated with the reversal of interstitial fibrosis and decreased expression of collagen Ia and Tgf- $\beta$ 1 in mice with a cardiac troponin T mutation (123) who received losartan treatment (124).  $\beta\text{-MHC}^{403/+}$  transgenic rabbits were administered the HMG-CoA reductase inhibitor, simvastatin, for 12 weeks. As compared with placebo-treated transgenic

**FIGURE 47-7** Treatment with anti-TGF- $\beta$  neutralizing antibody (TGF- $\beta$  NAb) or losartan prevents the development of cardiac hypertrophy and fibrosis. Upper panel. Whole heart sections from mice treated with control IgG (Rb IgG) shows fibrosis (blue, Mason trichrome stain), unlike mice treated with TGF- $\beta$  NAb or losartan. Lower panel. Histologic sections stained with wheat-germ agglutinin (green) to demonstrate fibrosis and DAPI (blue) from BrdU-treated mice show nonmyocyte cell proliferation (magenta) in Rb IgG-treated mice that is reduced by TGF- $\beta$  NAb or losartan treatment. (Adapted with permission from Teekakirikul, P.; Eminaga, S.; Toka, O., et al. *Cardiac Fibrosis in Mice with Hypertrophic Cardiomyopathy Is Mediated by Non-myocyte Proliferation and Requires Tgf- $\beta$* . J. Clin. Invest. **2010**, 120, 3520–3529, with permission of The American Society for Clinical Investigation.)

**FIGURE 47-8** A model for fibrosis and diastolic dysfunction from HCM sarcomere gene mutations. Mutant myocytes have increased biophysical properties and abnormal  $\text{Ca}^{2+}$  homeostasis, factors that trigger mechanical and/or biochemical signals that activate gene transcription, e.g. Tgf- $\beta$ . Tgf- $\beta$  then stimulates nonmyocyte proliferation and expression of profibrotic molecules. Activated nonmyocyte cells secrete profibrotic factors that expand the interstitium, generate more stresses imposed on mutant myocytes, and promote myocyte death with resultant focal scarring. Tgf- $\beta$ -mediated increased interstitial and focal fibrosis may contribute to diastolic dysfunction in HCM hearts. Antagonism of Tgf- $\beta$  signaling by a neutralizing antibody (NAb) or losartan attenuates nonmyocyte proliferation and profibrotic gene expression, thereby preventing cardiac fibrosis. (Adapted with permission from Teekakirikul, P.; Eminaga, S.; Toka, O., et al. *Cardiac Fibrosis in Mice with Hypertrophic Cardiomyopathy Is Mediated by Non-myocyte Proliferation and Requires Tgf- $\beta$* . J. Clin. Invest. **2010**, 120, 3520–3529, with permission of The American Society for Clinical Investigation.)

animals, simvastatin therapy was associated with regression of hypertrophy and fibrosis as well as improved cardiac function and decreased intracardiac filling pressures. In addition, levels of activated stress-responsive signaling kinases (ERK 1/2) were reduced, suggesting that these pathways that trigger myocardial fibrosis and dysfunction may be modulated to improve disease expression (123).

Elevated myocardial aldosterone and aldosterone synthase mRNA levels have been demonstrated in both

humans with HCM and in cTnT-Q (123) mice. Treatment with the mineralocorticoid receptor antagonist, spironolactone, reversed interstitial fibrosis, attenuated myocyte disarray, and improved diastolic function (125). These promising results in animal studies highlight the importance of ongoing collaborative basic science and human clinical investigation to further our understanding of the pathophysiology of HCM and to allow for the development of novel treatment strategies for human disease.

## 47.2.6 New Paradigms of Inherited Cardiac Hypertrophy

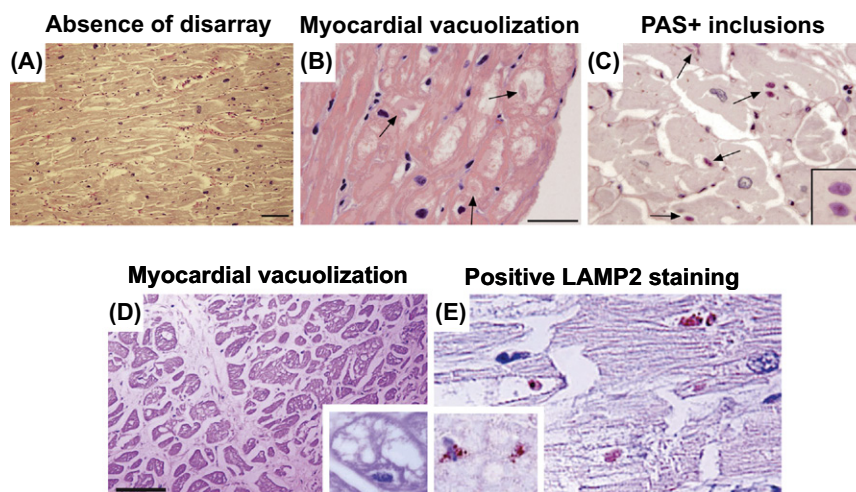

**47.2.6.1 Deficits of Energy Production and Regulation.** Gene mutations have been described in non-sarcomere proteins that produce clinical manifestations that mimic HCM phenotypes. Unexplained LVH that occurs with conduction abnormalities (progressive atrioventricular block, atrial fibrillation, and ventricular pre-excitation/Wolff–Parkinson–White syndrome) can be due to mutations in the  $\gamma$ -2 regulatory subunit (PRKAG2) of adenosine monophosphate (AMP)-activated protein kinase (AMPK), an enzyme involved with glucose metabolism, as well as mutations in the X-linked lysosome associated membrane protein (LAMP2) gene (12,126,127). In these patients, ventricular pre-excitation typically occurs early in life and is often symptomatic. These pathologies are not genetically related to the pre-excitation that occurs in isolated WPW (128), an arrhythmia that occurs in structurally normal hearts. Despite an increased prevalence of WPW in first-degree relatives of affected individuals, the genetic cause(s) of isolated WPW has not been elucidated (129).

Several important differences help to discriminate between HCM and PRKAG2 cardiomyopathies. The myocyte histopathology produced by PRKAG2 mutations lacks both the myocyte disarray and markedly increased fibrosis found in HCM and instead shows glycogen and amylopectin accumulation (Figure 47-9). Progressive cardiac conduction system disease occurs with increasing age in patients with PRKAG2 mutations, such that permanent pacemaker implantation is required in 30% of affected individuals (130). Severe

clinical outcomes were noted in a subset of patients with PRKAG2 mutations, including progression to end-stage heart failure or transplantation and sudden cardiac death.

LAMP2 mutations produce profound cardiac remodeling. Encoded on chromosome X, LAMP2 mutations are distinguished from HCM (Figure 47-10; Table 47-2) caused by sarcomere mutations due to the presence of ventricular pre-excitation, male-predominance, earlier age of presentation, striking LVH that can be massive (LV wall thickness >50mm) and is typically concentric, prominent voltage on EKGs and prevalent arrhythmias and progression to heart failure (131,132). LAMP2 cardiomyopathy causes early death in affected males, typically before age 30. Despite male preponderance, LAMP2 cardiomyopathy can also occur in female patients, presumably due to X-inactivation of the normal chromosome. LAMP2 mutations produce the multisystemic disorder, Danon disease, in which neurologic, skeletal muscle, and hepatic involvement occur with cardiomyopathy.

Despite the common finding of cardiac hypertrophy, LVH caused by PRKAG2 or LAMP2 mutations define a new paradigm for hypertrophic remodeling. This is a disease entity distinct from HCM caused by sarcomere protein mutations. Despite sharing a phenotype of cardiac hypertrophy with HCM, the different molecular signaling pathways triggered by PRKAG2 and LAMP2 mutations are likely to be different from those produced by sarcomere gene mutations. These differences suggest that the clinical approach to individuals with PRKAG2 and LAMP2 mutations should not be predicated on

**FIGURE 47-9** Histopathology of glycogen storage cardiomyopathies. A and B. PRKAG2 mutations cause nonmembrane bound vacuoles (arrows) that stain for glycogen and amylopectin in myocytes. There is less fibrosis than in HCM and no myocyte disarray. C. Homogenous inclusions within vacuoles (arrows and inset) stained positive with PAS are mostly diastase-resistant. (Reproduced from Arad, M.; Benson, D. W.; Perez-Atayde, A. R., et al. *Constitutively Active AMP Kinase Mutations Cause Glycogen Storage Disease Mimicking Hypertrophic Cardiomyopathy*. *J. Clin. Invest.* **2002**, 109, 357–362, with permission of The American Society for Clinical Investigation.) D. LAMP2 mutations cause myocyte enlargement with prominent pleomorphic nuclei, and numerous cytoplasmic vacuoles. A vacuolated myocyte with a “spider cell” (inset) resembles rhabdomyoma cells. E. Immunohistochemical staining with LAMP2-specific antibodies exhibits positive (red) staining within vacuoles. (Adapted with permission from Arad, M.; Maron, B. J.; Gorham, J. M., et al. *Glycogen Storage Diseases Presenting as Hypertrophic Cardiomyopathy*. *N. Engl. J. Med.* **2005**, 352, 362–372.)

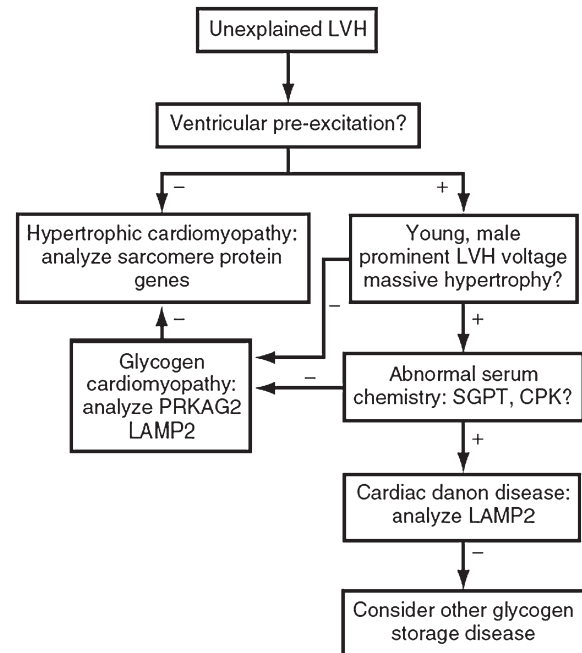

management tenets of HCM. An algorithm to differentiate HCM from glycogen storage cardiomyopathies is illustrated in Figure 47-11.

**47.2.6.2 Animal Models for PRKAG2 Cardiomyopathy.** A transgenic mouse model harboring the PRKAG2 Asn488Ile mutation under the cardiac  $\alpha$ -MHC promoter was constructed and recapitulated hallmarks of human

disease (133). Transgenic mice exhibited elevated AMPK activity, increased glycogen accumulation, massive LVH, progressive impairment of contractility, and ventricular pre-excitation and sinus node dysfunction. Ventricular pre-excitation occurred postnatally within the first

**FIGURE 47-10** LAMP2 mutations are associated with striking evidence of LVH. A. An electrocardiogram demonstrates a short PR interval, delta waves, and prominent voltage (R waves >50mm in precordial leads V4 and V5). B. The parasternal, long-axis view of an echocardiogram shows marked hypertrophy (maximal left ventricular wall thickness, >35mm) involving the interventricular septum and posterior left ventricular wall. (Adapted with permission from Arad, M.; Maron, B. J.; Gorham, J. M., et al. *Glycogen Storage Diseases Presenting as Hypertrophic Cardiomyopathy*. *N. Engl. J. Med.* **2005**, 352, 362–372.)

**FIGURE 47-11** An algorithm for the diagnosis of unexplained left ventricular hypertrophy (LVH). HCM is suggested by an autosomal dominant pattern of inheritance of LVH that occurs without systemic manifestations or conduction system abnormalities. Glycogen storage cardiomyopathy is suggested by the presence of ventricular pre-excitation in conjunction with unexplained LVH. PRKAG2 mutations are suggested by autosomal dominant inheritance and the absence of systemic manifestations. X-linked LAMP2 mutations are suggested by early-onset of cardiac-manifestations (Figure 47-10), male gender and progressive abnormalities in liver, musculoskeletal or neurologic function. (Adapted with permission from Arad, M.; Maron, B. J.; Gorham, J. M., et al. *Glycogen Storage Diseases Presenting as Hypertrophic Cardiomyopathy*. *N. Engl. J. Med.* **2005**, 352, 362–372.)

Data from Arad, M.; Maron, B. J.; Gorham, J. M., et al. *Glycogen Storage Diseases Presenting as Hypertrophic Cardiomyopathy*. *N. Engl. J. Med.* **2005**, 352, 362–372.

month of life. A continuous thick fibrous layer (annulus fibrosis), which typically electrically insulates the ventricles from the atria was rendered discontinuous by vacuolated myocytes in transgenic mice (133,134). Phenotypic manifestations are mediated through enhanced activity of  $\alpha 2$ -subunit complexes (135). To assess whether cardiomyopathy, ventricular pre-excitation, and conduction system disease in PRKAG mutant hearts are prevented or reversed by glycogen modulation, the tetracycline-regulated transcriptional activator system was used in this transgenic mouse (PRKAG2<sup>Asn488Ile</sup>). It appeared that PRKAG2 cardiomyopathy, cardiac dysfunction, and conduction deficits were reversible mechanisms. Transgene suppression during early postnatal development completely prevented the emergence of accessory electrical pathways but not cardiomyopathy or progressive conduction system degeneration (136). These data suggest that developmental timing of glycogen depletion is critical to prevent accessory pathway, and imply that myocardial dysfunction and conduction system disease in PRKAG2 cardiomyopathy could potentially be treated by modulation of glycogen content, a viable alternative treatment option to device implantation and cardiac transplantation for patients with glycogen storage cardiomyopathy and arrhythmias.

These non-sarcomere cardiomyopathies now become part of a subgroup of glycogen storage diseases (Figure

47-12), such as Pompe disease, a glycogen storage disease with acid maltase deficiency in infants and Fabry disease, an X-linked recessive glycosphingolipid disorder caused by the lysosomal enzyme  $\alpha$ -galactosidase A deficiency (137). Many other mutations leading to LV hypertrophy by defects in sarcomere, metabolic, and other genes remain to be discovered.

### 47.2.7 Diagnosis

The identification of unexplained LVH, typically via echocardiographic imaging, has traditionally formed the basis for the diagnosis of HCM. However, the presence of LVH is not an infallible marker for disease and is not universally present throughout life or in all individuals with sarcomere gene mutations. Thus, unexplained LVH is not the most specific or sensitive manifestation of HCM and further definition of the full spectrum of the HCM phenotype is required. Animal and human studies have indicated that diastolic abnormalities are present prior to the development of LVH (88,121,122,138). Biochemical abnormalities, namely alterations in intracellular calcium handling, may represent an even more fundamental manifestation of sarcomere gene mutations (94,99).

Myocardial fibrosis, a pathological hallmark of HCM, contributing to sudden cardiac death, cardiac

**FIGURE 47-12** Muscle glycogen metabolism pathways associated with cardiac diseases. Glucose enters the myocyte through transmembrane transport proteins and undergoes phosphorylation by hexokinase. It then enters pathways for glycolysis or glycogen synthesis by glycogen synthase. Glycogen, a branched glucose polymer, is a dynamic energy reservoir for muscles, as dictated by enzyme activity to change phosphorylation state. Glycogen metabolism is also influenced by AMP-activated protein kinase (regulates glucose uptake and fatty-acid oxidation via acetyl CoA carboxylase) and by lysosome activity. Defects in pathways of glycogen degradation (phosphorylase, phosphoglucomutase, phosphofructokinase, phosphoglycerate kinase, lactic dehydrogenase, and brancher/debrancher enzymes) result in glycogen accumulation. Mutations in PRKAG2 (the regulatory  $\gamma$  subunit of AMP kinase) or LAMP2 may cause glycogen accumulation resulting in cardiac hypertrophy and electrophysiological abnormalities. (Adapted with permission from Arad, M.; Maron, B. J.; Gorham, J. M., et al. *Glycogen Storage Diseases Presenting as Hypertrophic Cardiomyopathy*. N. Engl. J. Med. 2005, 352, 362–372.)

arrhythmias, LV dysfunction, and progressive heart failure (139–141) can be visualized with histologic evaluation and noninvasively with gadolinium-enhanced cardiac MRI (Figure 47-13) (105,142). Recent studies of serologic biomarkers of collagen metabolism in asymptomatic carriers of sarcomere mutations indicate that profibrotic milieu is significantly enhanced, preceding the development of LVH and myocardial fibrosis detectable on MRI (142). These findings suggest that sarcomere mutations have a prominent effect on the heart prior to

the onset of LVH. Their clinical and diagnostic implications may include identifying and monitoring persons at risk for cardiac complications as well as developing novel therapeutic strategies to attenuate fibrosis in HCM.

Genetic testing allows for precise and age-independent identification of individuals at risk for developing HCM and should be incorporated into the contemporary diagnosis of this disorder. Currently genetic diagnosis is accomplished by direct DNA sequence analysis of the exons and intron/exon boundaries of sarcomere

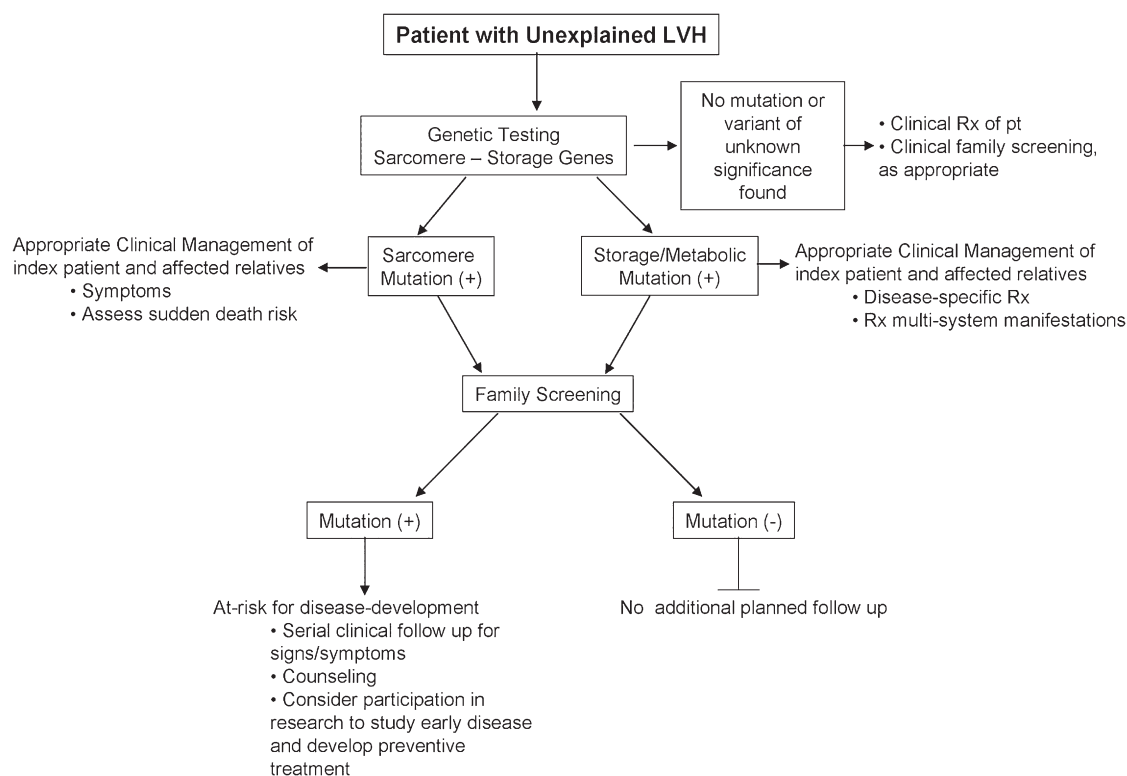

**FIGURE 47-13** Gadolinium-enhanced cardiac MRI in patients with overt HCM and in preclinical mutation carriers. A, C, and E. Young individuals with a sarcomere gene mutation have neither LVH nor late gadolinium enhancement of the myocardium. B, D, and F. Overt HCM shows a markedly thickened septum (B, arrow) associated with areas of heterogeneous delayed enhancement, which involves the anteroseptum (D, arrows) and the inferoseptum (D and F, arrows). LA, left atrium; LV, left ventricle; RA, right atrium; and RV, right ventricle. (Reproduced with permission from Ho, C. Y.; Lopez, B.; Coelho-Filho, O. R., et al. *Myocardial Fibrosis as an Early Manifestation of Hypertrophic Cardiomyopathy*. N. Engl. J. Med. **2010**, 363, 552–563.)

genes in order to identify potential disease-associated sequence variants. Once a sequence variant is identified, pathogenicity is typically determined by verifying that the sequence or structure of the encoded protein is altered, that the sequence variant absent from at least 2000 ethnically matched chromosomes from unaffected subjects, and that appropriate cosegregation with disease occurs in familial cases, or that the variant arises de novo. This is a daunting task that underscores the need for more efficient yet reliable techniques for screening large stretches of DNA. Application of emerging next generation sequencing technologies at subgenomic (up to ~200 genes) and whole exome/genome levels are increasingly allowing high-throughput clinical genetic screening and further discovery of novel causative and disease-modifying genes in patients with HCM. The identification of a sarcomere gene mutation in the appropriate clinical setting allows the definitive diagnosis of HCM and establishes the exact genetic etiology. Mutation confirmation can then be performed in family members in a straightforward manner. Individuals found to carry the family-specific mutation despite the absence of clinical manifestations are at risk for developing HCM and require longitudinal clinical follow-up as described later in this chapter. Such individuals should also be counseled of the 50% chance of transmission of the mutation to offspring. Family members who do not carry the mutation have no risk for developing HCM or

transmitting the condition. Longitudinal clinical follow-up is not necessary. An algorithm to incorporate clinical molecular genetic testing in the approach to patients and families with unexplained LVH is illustrated in Figure 47-14 (51).

There are significant limitations to this strategy of genetic diagnosis. Mutations in sarcomere genes, PRKAG2 and LAMP2 are thought to account for 60–75% of cases of inherited LVH. As such mutations are not detected in all individuals with unexplained LVH. A negative result from molecular screens can not exclude a genetic etiology, but simply eliminates previously identified genes from the list of suspects. Furthermore, in the absence of specific clinical correlates that are associated with genotype, this information remains most useful in establishing certain diagnosis of HCM or future risk for developing the disease. Although management of mutation carriers without clinical disease remains an emerging clinical field, longitudinal follow-up of this subset population is essential and limitations on competitive athletic participation is probably prudent. Continued efforts to elucidate how gene mutations lead to HCM may ultimately allow development of new strategies of disease management that will aim to alter the phenotype rather than merely palliating symptoms. Genetic diagnosis will play a crucial role in allowing us to identify and target therapy to individuals with gene mutations but with clinically undetectable disease.

**FIGURE 47-14** An algorithm for incorporating clinical molecular genetic testing in the approach to patients and families with unexplained left ventricular hypertrophy (LVH). (Reproduced with permission from Ho, C. Y. *Is Genotype Clinically Useful in Predicting Prognosis in Hypertrophic Cardiomyopathy?* *Circulation* **2010**, 122, 2430–2440.)

### 47.2.8 Management

There are two major aspects to the management of HCM: alleviation of symptoms and assessment of the risk for sudden cardiac death. Medical therapy is the cornerstone of treatment for symptomatic HCM and typically incorporates agents such as  $\beta$ -adrenergic and calcium channel antagonists to increase diastolic filling time, slow the heart rate, decrease contractility, and help to normalize intracardiac filling pressures. However, dihydropyridine calcium channel antagonists that have vasodilating effect should not be administered in patients with LVOT because they can enhance the severity of LVOT by decreasing afterload. Diuretics may be used judiciously for symptoms of congestion; however, due to altered LV compliance characteristics, overly aggressive diuresis may be associated with an abrupt fall in blood pressure and worsening of LV outflow tract obstruction. Disopyramide may also be used to attempt to alleviate outflow tract obstruction due to its negative inotropic effects. Afterload reduction should be avoided in patients with outflow tract obstruction or dynamic intracavitary gradients as obstructive physiology may be worsened.

Whether early pharmacological intervention of the molecular signals triggered by sarcomeric mutations might attenuate ventricular remodeling and symptoms has become an important question. Based upon experimental studies (94,99,115), clinical studies of sarcomere-mutation carriers without overt HCM have been characterized. Serum biomarker profiles revealed elevated levels of C-terminal propeptide of type I procollagen (PICP), a finding that suggests that the profibrotic state identified in the hearts of mouse HCM models also occurs in prehypertrophic humans with sarcomere mutations (142). Pharmacologic interventions (that parallel losartan treatment in HCM mice) are planned to assess whether attenuation of profibrotic signals in prehypertrophic patients impacts the emergence of overt disease.

An HCM prevention trial (*Clinical Trials* website) is underway, which uses diltiazem to modify calcium cycling based on studies of HCM mouse models (94). A pilot cohort of 40 prehypertrophic patients with any molecularly identified sarcomere mutation treated with either diltiazem or placebo will be assessed for signs of the development of HCM, including diastolic dysfunction, electrocardiographic abnormalities, and LVH. Estimated study completion date is December 2013.

Mechanical relief of obstructive physiology is warranted in HCM patients with persistent symptoms despite good medical regimens. Interventions to relieve outflow tract obstruction include surgical septal myectomy or catheterization-based alcohol septal ablation (16,143). Careful consideration of the mechanism of obstruction is warranted to assess the potential benefit from invasive procedures and to choose the appropriate strategy.

A number of clinical indicators of increased risk for sudden death have been identified including a prior

history of cardiac arrest or sustained ventricular tachycardia; unexplained syncope; significant nonsustained ventricular tachycardia on ambulatory monitoring; an abnormal blood pressure response to exercise in patients younger than 50 years; massive LVH (>30–35 mm); and a family history of recurrent SCD or identification of a malignant genotype. However estimation of an individual's risk is imprecise. If two or more risk factors are present, an increased risk of SCD is present with an estimated annual mortality of 4–6% (14,31,144). The positive predictive value of each risk factor individually is relatively low. In contrast, the negative predictive value of these risk factors is more useful (18)—if none of these risk predictors is present, the individual is likely at low annual risk for sudden death (<1%). Sudden death may be the initial presenting symptom of HCM or occur in only mildly symptomatic patients. Although sudden death has been associated with vigorous physical activity, many episodes have occurred in the setting of only mild or no exercise. Implantation of an implantable cardioverter-defibrillator (ICD) is effective in decreasing the risk of sudden death from lethal arrhythmias in appropriate individuals (145).

Given the familial nature of HCM, clinical screening of first-degree relatives of affected individuals is recommended. This consists of history, physical examination, 12-lead EKG, and echocardiography. As the penetrance of LVH is age-dependent, the lack of clinical findings on initial assessment does not exclude the possibility of disease or the inheritance of an underlying sarcomere mutation. Serial screening and longitudinal follow-up is required to evaluate for the development of phenotypic manifestations with aging. The age at which screening should begin is not clearly defined, and the following strategy has been proposed for familial HCM (146). Because overt manifestations are unusual in early childhood, screening of children under the age of 12 years is optional unless there are symptoms, a malignant family history of premature HCM-related death, early onset hypertrophy or other serious complications, or if the child is a competitive athlete. Serial screening every 12–18 months is recommended between the ages of 12 and 21 years and then follow-up should be continued at 3- to 5-year intervals thereafter until clinical manifestations develop or until a more definitive genetic diagnosis is established. Recent availability of clinical HCM genetic testing at many molecular diagnostic laboratories (*Gene Tests* website), should promote longitudinal clinical evaluation only to those at risk individuals who have inherited a pathogenic mutation.

## 47.3 DILATED CARDIOMYOPATHY

Pathologic remodeling of the heart resulting in increased chamber volume and diminished contractile function is termed DCM (Figure 47-1). Cardiac mass is increased due to enlargement of the cardiac chambers with only

modest increase in ventricular wall thickness. Histopathologic changes may be relatively subtle with only minor myocyte hypertrophy, degeneration, and interstitial fibrosis. The less distinctive clinical manifestation of DCM compared with hypertrophic remodeling has challenged precise characterization.

DCM that occurs in the absence of disorders that may cause cardiac dilation and dysfunction (coronary artery disease, alcohol abuse, untreated tachycardia, thyroid disease, viral myocarditis, and infiltrative disorders such as hemochromatosis) leads to the diagnosis of “idiopathic” DCM, a disorder that often is recognized in families. Increasingly, the application of molecular genetic studies to “idiopathic” DCM has resulted in the identification of underlying gene mutations. There is considerably more genetic diversity in DCM than in gene mutations that trigger hypertrophic remodeling.

### 47.3.1 Prevalence

The prevalence of genetic DCM is unclear, largely because most estimates assess primarily symptomatic disease, even though DCM, like HCM, can be clinically silent for many years. DCM occurs as a sporadic or familial trait. Familial cardiomegaly was first reported in 1948 and with systematic screening of family members in the 1990s more accurate estimates of its prevalence emerged. Clinical studies in which first-degree relatives of DCM probands were assessed with physical examination, 12-lead EKG, and echocardiography suggest a familial component in 30–50% of cases (147–150), implicating a genetic etiology. However, pathogenic mutations have been identified in only 20–30% of all DCM cases (151). Amongst 235 consecutive unrelated probands with DCM presenting to a single center between 1995 and 2002, clinical evaluations determined that 102/235 (43%) cases were familial based on a family history of premature sudden death or clinical findings of cardiovascular involvement in at least one other relative. Of these, over 85% demonstrated autosomal dominant inheritance (150,152).

### 47.3.2 Pathology

Typical anatomic findings of DCM are four-chamber cardiac enlargement without proportional hypertrophy of the ventricular walls (Figure 47-1). The histopathology is generally nonspecific with degenerating myocytes with mild to moderate hypertrophy and variable amounts of interstitial fibrosis. Although small foci of myocyte disarray may be found, the proportion is much below that required to establish the diagnosis of HCM. This lack of disarray is an important discriminating feature to differentiate true DCM from the end stage, “burnt-out” phase of HCM in which a small proportion of patients exhibit regression of LVH, cavity enlargement, and diminished left ventricular systolic dysfunction, although the myocyte disarray characteristic of HCM remains present.

## 47.3.3 Phenotype and Natural History

**47.3.3.1 Phenotype.** Clinical manifestations may be somewhat protean, particularly in the early stages of disease. Characteristic symptoms include exertional dyspnea, fatigue, orthopnea, and lower extremity edema. The age of onset can range from early childhood to late adulthood, although most patients present during the fourth or fifth decades of life. Familial DCM may be associated with additional phenotypes that cosegregate with disease (153), including additional cardiac involvement (mitral valve prolapse and conduction system disease) and extra-cardiac conditions (sensorineural hearing loss and muscular dystrophies). These additional manifestations may be expressed in advance of cardiac dilation or dysfunction and therefore serve as surrogate parameters to assign phenotypic status.

### 47.3.4 Natural History

The substantial genetic and clinical heterogeneity of DCM accounts for a natural history that is highly variable. Specific genotype–phenotype correlations are in general not well delineated. The spectrum of manifestations may range from asymptomatic left ventricular enlargement or dysfunction to progressive heart failure requiring cardiac transplantation. DCM is the most common underlying diagnosis in patients requiring cardiac transplantation in the United States and a common cause of heart failure with a world-wide prevalence of ~36.5 per 100,000 (154). Life expectancy in DCM is reduced due to severe heart failure or sudden death.

### 47.3.5 Genetics

The genetics of DCM are much more diverse than in HCM and remained incompletely defined. The most common mode of inheritance of familial DCM is autosomal dominant, but infrequent autosomal recessive, X-linked, and mitochondrial transmissions have been described (Table 47-3). A variety of molecular pathways have been identified that ultimately result in dilated remodeling of the heart. Mutations in a broad group of diverse genes have been implicated. These genes may be divided broadly into alterations of force generation and transmission, alterations of energy production and regulation, and alterations of intracellular calcium handling.

#### 47.3.5.1 Deficits in Force Generation and Transmission

The foundation of cardiac function is the generation of contractile force by the sarcomere and the transmission of force to the extracellular matrix. DCM can occur from mutations in genes that encode components of the force-generating sarcomere or in genes that encode proteins involved in forces transmission through the extracellular matrix (Figure 47-15). Notably, sarcomere protein gene mutations produce either DCM or HCM, depending on

**TABLE 47-3 Gene Mutations Associated with Dilated Cardiomyopathy<sup>a</sup>**

Gene	Protein	OMIM	% of DCM Caused by Mutations	Associated Phenotypes <sup>b</sup>
<b>Autosomal Dominant</b>				
ACTC1	$\alpha$ -cardiac actin	102540	<1%	
DES	Desmin	125660	<1%	Desminopathy, Myofibrillar myopathy
LMNA	Lamin-A/C	150330	7–8%	Partial lipodystrophy, CMT2B1, Emery–Dreifuss muscular dystrophy, Hutchinson–Gilford progeria syndrome, LGMD1B
SGCD	$\delta$ -sarcoglycan	601411	Unknown	Delta sarcoglycanopathy (LGMD2F)
MYH7	Myosin-7	160760	5–8%	Laing distal myopathy
TNNT2	Troponin T	191045	2–4%	
TPM1	$\alpha$ -tropomyosin	191010	Unknown	
TTN	Titin	188840	Unknown	Congenital myopathy, hereditary myopathy with early respiratory failure, LGMD, tibial muscular dystrophy
VCL	Vinculin	193065	Unknown	
MYBPC3	Cardiac myosin-binding protein C	600958	Unknown	
PLN	Cardiac phospholamban	172405	Unknown	
LDB3	LIM domain-binding protein 3	605906	Unknown	
ACTN2	$\alpha$ -actinin-2	102573	Unknown	
CSRP3	Cysteine and glycine-rich protein 3	600824	Unknown	
MYH6	Myosin-6	160710	Unknown	
ABCC9	ATP-binding cassette transporter sub-family C member 9	601439	Unknown	
TNNC1	Troponin C	191040	Unknown	
TCAP	Telethonin	604488	Unknown	LGMD2G
SCN5A	Sodium channel protein type 5 subunit alpha	600163	2–4%	Long QT syndrome type 3, Brugada syndrome, idiopathic ventricular fibrillation, sick sinus syndrome, cardiac conduction system disease
PSEN1	Presenilin-1	104311	<1%	Early-onset Alzheimer disease
PSEN2	Presenilin-2	600759	<1%	Early- and late-onset Alzheimer disease
FCMD	Fukutin	607440	Unknown	Fukuyama congenital muscular dystrophy
<b>X-Linked</b>				
DMD	Dystrophin	300377	Unknown	Dystrophinopathies (Duchenne muscular dystrophy, Becker muscular dystrophy)
TAZ (G4.5)	Tafazzin	30094	Unknown	Barth syndrome, endocardial fibroelastosis type 2, familial isolated noncompaction of the left ventricular myocardium
<b>Autosomal Recessive</b>				
TNNI3	Cardiac troponin I	191044	Unknown	Restrictive cardiomyopathy

LGMD, limb-girdle muscular dystrophy.

<sup>b</sup>Other phenotypes caused by mutation in the same gene.

the precise residue that is altered by mutation and the resultant impact on contractile functions.

#### 47.3.5.2 Sarcomere Protein Mutations.

**47.3.5.2.1 Cardiac Actin (ACTC1).** Mutations in ACTC1 associated with DCM were first identified by candidate gene screening approaches. ACTC1 mutations are associated with early onset autosomal dominant DCM that occurs without additional cardiac or extracardiac manifestations (57,67). As described earlier in this chapter, actin plays a central role in both the production and transmission of the contractile force of the sarcomere. DCM-causing mutations in actin are hypothesized to disrupt force transmission, as they involve amino acid residues that dictate actin-cytoskeleton interactions (at

the Z line of the sarcomere). Rare actin mutations that alter actin-myosin interactions and presumably force generation may cause HCM (38,153,155).

**47.3.5.2.2  $\beta$ -Myosin Heavy Chain (MYH7).** This sarcomere protein was first implicated in DCM via genetic linkage studies of a large family with DCM that mapped to chromosome 14q (156). A  $\beta$ -myosin heavy chain missense mutation was identified in that family and subsequently in other DCM families that altered residues that have not been implicated in HCM. Biophysical analyses of DCM mutations in  $\beta$ -myosin heavy chain (e.g. Ser532Pro) indicate that these can diminish force generation by disruption of actomyosin binding. In contrast, another DCM mutations (e.g. Phe764Leu)

**FIGURE 47-15** Mutations in components of the myocyte cytoskeleton and extracellular matrix are associated with DCM and heart failure. Contractile force generated by the sarcomere is propagated through the actin cytoskeleton and dystrophin into the dystrophin-associated glycoprotein complex ( $\alpha$ - and  $\beta$ -dystroglycans,  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -sarcoglycans, caveolin-3, syntrophin, and dystrobrevin). Protein elements of the desmosome, plakoglobin, desmoplakin, and plakophilin-2 provide functional and structural contacts among neighboring cells. Intermediate filament proteins, including desmin, link this network to the nuclear membrane, where lamin A/C is located. (Reproduced from Morita, H.; Seidman, J.; Seidman, C. E. *Genetic Causes of Human Heart Failure*. J. Clin. Invest. **2005**, 115, 518–526, with permission of The American Society for Clinical Investigation.)

located in the head-neck hinge region of myosin alters the mechanics of contractile efficiency or force transmission (157).

**47.3.5.2.3 Cardiac Troponin T (TNNT).** DCM mutations in cardiac troponin T were discovered via candidate gene screening approaches. An in-frame deletion of a lysine residue located in the putative  $\text{Ca}^{2+}$ -sensitive troponin C binding region ( $\Delta\text{Lys210}$ ) originally identified in two unrelated DCM kindreds (156) has been subsequently identified in several other DCM kindreds. Missense mutations in cardiac troponin T missense mutations have been described. Clinical phenotypes associated with cardiac troponin T mutations are variable. While some mutation carriers have only modest clinical symptoms throughout life, others develop severe manifestations of DCM early in life, increased risk of sudden cardiac death, and rapid progression of heart failure (152).

**47.3.5.2.4 Cardiac Troponin I (TNNI3).** Mutations in cardiac troponin I are an uncommon cause of familial DCM. cTnI mutations Lys36Gln and Asn185Lys accounted for severe and early-onset DCM in two families (158). Functional studies demonstrate that both mutations diminished  $\text{Ca}^{2+}$  sensitivity and maximum ATPase activities, findings that are comparable with deficits produced by other DCM mutations in thin filament mutant proteins.

**47.3.5.2.5  $\alpha$ -Tropomyosin (TPM1).** Mutations in  $\alpha$ -tropomyosin were initially associated with DCM via a candidate gene screening approach of 350 probands with familial and sporadic DCM (159). Subsequent TPM1 mutations were identified to segregate with disease in DCM families. Clinical manifestations of DCM caused by some TPM1 mutations can vary considerably with patient age (160). Childhood presentation includes severe heart failure and high risk for sudden death that can necessitate transplantation. But with medical therapies remarkable recovery has been documented followed by long term survival with minimal symptoms and modest LV dysfunction.

In contrast to HCM-associated  $\alpha$ -tropomyosin mutations, which are typically localized to force generation regions involved in troponin T binding and  $\text{Ca}^{2+}$  sensitivity, some DCM mutations in TPM1 alter amino residues involved in surface polarity, therein disrupting actin interactions and compromising force transmission. Recent biochemical analyses of human DCM TPM1 mutations (160) confirm this model and also demonstrated marked reductions in  $\text{Ca}^{2+}$  sensitivity and affinity as well as lower maximum activation, changes that are predicted to reduce force generation.

**47.3.5.2.6 Titin (TTN).** The largest protein and one of the most abundant striated muscle proteins in humans, is the 3-kDa molecule (161) encoded by the TTN gene on chromosome 2. One titin protein spans an entire half of the sarcomere from Z-disc to M-line and functions in assembling contractile filaments, providing elasticity through serial spring-like elements and the majority of passive force, regulating active contractile force (162–165).

Due to the very large size of TTN (>100 kb of coding sequence), this gene has been studied in few DCM patients and to date fewer than 10 mutations (nonsense and missense) have been reported (166,167). Recessive mutations in TTN gene have been also reported in DCM that occurs in the context of congenital myopathies, including hereditary myopathy with early respiratory failure, tibial muscular dystrophy, and limb-girdle muscular dystrophy (168–170). Mechanisms by which different titin mutations produce isolated DCM or disease affecting multiple striated muscles are poorly understood.

**47.3.5.3 Intermediate Filament Mutations.** Intermediate filament proteins (Figure 47-15) connect actin to the dystrophin-sarcoglycan complex beneath the plasma

membrane of all muscle cells. Components of the sarco-glycan complex also extend outside of myocytes to the extracellular matrix (153). As such, mutations in intermediate filament elements are recognized causes of skeletal muscular dystrophies. Varying degrees of cardiac involvement are also seen.

**47.3.5.3.1 Desmin (DES).** The type III intermediate filament protein desmin is a 470-amino-acid muscle-specific protein that is expressed in cardiac and skeletal muscle. It is encoded by the DES gene, an 8.4-kb gene with nine exons; the resultant protein has a structure typical of intermediate filaments with a central  $\alpha$ -helical coiled-coil rod domain and flanking non-helical amino and carboxy terminals (38). Missense mutations in DES have been associated with familial desmin-related myopathy characterized by skeletal myopathy, cardiac conduction system abnormalities, restrictive cardiomyopathy, and intracytoplasmic accumulation of desmin-reactive deposits. Recent studies suggest that the ubiquitin-proteasome system plays a causative role in desmin-related cardiomyopathy, marked by an accumulation of desmin in cardiac muscle (171).

**47.3.5.3.2 Dystrophin (DMD).** Dystrophin is a large cytoskeletal protein that is expressed primarily in muscle. Its function is incompletely understood but thought to involve force transduction and membrane stabilization. Dystrophin is encoded by the DMD gene, the largest known gene at a length of 2.4 Mb on chromosome X (38). DMD mutations were first described as the genetic etiology of Duchenne muscular dystrophy and less severe phenotype called Becker muscular dystrophy. Duchenne muscular dystrophy is an X-linked recessive disorder with a prevalence of one in 3500 male births (172). Disease onset occurs in childhood with development of altered gait, progressive weakness of pelvic, femoral, shoulder girdle, neck flexor, and trunk muscles such that affected children may be wheelchair-dependent by adolescence. Cardiac involvement may consist of cardiomyopathy and conduction disease and typically develops later in the course of disease.

An X-linked primary DCM may also be caused by dystrophin mutations. The prevalence of DMD mutations in DCM is unclear. A study of adult onset DCM revealed dystrophin mutations in 13/201 probands. There was evidence of inherited disease in four of these cases (173). Affected males typically present in late adolescence with heart failure, which is often rapidly progressive and associated with premature death. Clinically evident skeletal myopathy may not be present; however, elevation of serum creatine kinase levels is often present. Female carriers have a predictably less severe phenotype with slower progression and later onset of DCM. A variety of mutation types have been described, most clustered at the amino terminal, including the promoter region, as well as the mid-rod domain (174). Quantitative and qualitative defects in protein expression have

been demonstrated (174). The basis for the cardiac selective phenotype is unclear.

**47.3.5.3.3 Sarcoglycans.** The dystrophin-associated glycoprotein complex is composed of  $\alpha$ - and  $\beta$ -dystroglycans,  $\alpha$ -,  $\beta$ -,  $\gamma$ - and  $\delta$ -sarcoglycans, caveolin-3, syntrophin, and dystrobrevin. Via dystrophin and actin interactions, this complex serves to stabilize the sarcomere and transmit force to the extracellular matrix.

$\delta$ -Sarcoglycan is a 290-amino-acid protein encoded by the SGCD gene (>100 kb; eight exons). The protein has a small intracellular domain, a single membrane spanning domain, and a large extracellular carboxyl terminal (38). SGCD mutations were first associated with autosomal recessive limb girdle muscular dystrophy (175). Candidate gene approaches revealed the deletion mutation,  $\Delta$ Lys28 in a family with autosomal dominant DCM, sudden death, and heart failure, but no evidence of clinically obvious skeletal myopathy (176). Fukutin-related protein (FKRP) is necessary for the dystrophin glycoprotein complex to remain intact. Mutations in the FKRP gene produce a clinical spectrum ranging from limb girdle muscular dystrophy with DCM to DCM with slight muscle weakness (177).

**47.3.5.3.4 Z-Disc Associated and Intercalated Disc Proteins.** For contractile force to be generated, one end of the thin filament must be tethered. The Z-disc defines the sarcomere's lateral boundary where actin, titin, and nebulin filaments are anchored. Metavinculin assists in the attachment of titin to the plasma membrane and therefore plays a key role in the transmission of force.

**47.3.5.3.5 Metavinculin and Vinculin (VCL).** Splice variants of the 75-kb VCL gene give rise to metavinculin and vinculin. Vinculin is a ubiquitously expressed component of the subsarcolemmal costameres and intercalated discs; metavinculin is coexpressed exclusively in cardiac, skeletal, and smooth muscle (38). Altered expression levels are associated with heart failure (178,179) suggesting a role in disease pathogenesis. VCL mutations have been recently identified by systematic genetic screening of a cohort of 350 individuals with sporadic and familial DCM (180).

**47.3.5.3.6 LIM protein (MLP) and Cypher/ZASP (LDB3).** Several Z-disc proteins have been implicated in DCM, including  $\alpha$ -actinin which functions to align actin and titin from adjacent sarcomeres, muscle LIM protein (MLP, interacts with  $\alpha$ -actinin), and telethonin which interacts with titin. Collectively these molecules may serve a role as mechano stretch receptors (181). Mutations in these proteins have been implicated in DCM (181,182). Cypher/ZASP is another Z-disc protein that is encoded by LDB3. At least six different isoforms have been characterized that have variable expression in cardiac and skeletal muscle. Human LDB3 mutations can cause isolated DCM as well as in left ventricular non-compaction (LVNC), a related cardiomyopathy characterized by poor systolic function of a dilated left ventricle in which deep trabeculations are present (177,182).

#### 47.3.5.4 Nuclear Intermediate Filament Proteins.

**47.3.5.4.1 Lamin A/C (LMNA).** The inner aspect of the nuclear membrane contains a complex containing composed of emerin and lamin A/C protein. Lamin A and C are widely expressed intermediate-filament proteins that arise from alternate splicing of the human LMNA gene, a 24-kb gene spanning 12 exons, and directly bind emerin. The function of lamins is incompletely understood, but these molecules participate in maintaining the structural integrity of the nuclear membrane, reassembly of the nuclear membrane during mitosis, and interacting with other proteins, including tissue-specific transcription factors (183).

Dominant mutations in the lamin A and C proteins (isoforms encoded by the LMNA gene) cause 16 different diseases with phenotypic variability, including isolated DCM, cardiac and skeletal myopathies, lipodystrophy, peripheral neuropathy, and progeria (184). Mutations that disrupt the terminal amino acids of lamin A cause progeria, while other LMNA mutations can cause tissue-specific disorders via unknown mechanisms. Mutations in emerin produce X-linked and autosomal recessive Emery–Dreifuss muscular dystrophy, which is characterized by joint contractures, cardiac conduction abnormalities, and DCM.

Cardiac phenotypes are particularly prevalent in LMNA disorders, including dominant Emery–Dreifuss muscular dystrophy (185), limb girdle muscular dystrophy (186), and DCM with prominent conduction system involvement (progressive atrioventricular (AV) block and atrial arrhythmias) (187,188). Electrophysiologic deficits usually precede DCM and may be the only cardiac manifestation (189). Electrophysiologic defects include sinus node dysfunction, paroxysmal atrial fibrillation, progressive AV block and ventricular arrhythmias (173,186,188). Postmortem findings of myocardium and conduction system with LMNA mutations exhibit fibro-fatty infiltration of the atrioventricular node (188). Several mutations which create null alleles cause Emery–Dreifuss muscular dystrophy whereas most missense mutations associated with isolated cardiac disease are predicted to function through a dominant-negative mechanism (188,190).

#### 47.3.5.5 Alterations in Energy Production and Regulation.

**47.3.5.5.1 Mitochondrial Mutations.** Five major multiprotein complexes within the mitochondria generate ATP by oxidative phosphorylation. Thirteen components of the machinery involved in oxidative phosphorylation are encoded by 37 genes in the mitochondrial genome, rather than the nuclear genome. The interplay between cardiac energetics and metabolism and pathways of cardiac remodeling are just beginning to be deciphered. Mitochondrial gene mutations demonstrate matrilineal inheritance as the mitochondria are derived exclusively from the maternal cell lineage. Additionally, heteroplasmy may be present with mutations

affecting some but not all copies of the mitochondrial genome in any given cell. As a result, there is marked clinical diversity in the expression of mitochondrial gene mutations. Syndromic disorders are most common with dilated or hypertrophic cardiac remodeling occurring in conjunction with Kearns–Sayre syndrome (ptosis, ophthalmoplegia, and pigmentary retinopathy, proximal muscle myopathy, diabetes and additional hormonal deficits and cardiac conduction abnormalities), MELAS (mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes), and MERRF (myoclonic epilepsy with ragged-red fibers) (191). Less common predominant or exclusive cardiac disease has been described, particularly DCM (192–194).

Nuclear encoded metabolic mutations have been described in association with hypertrophic remodeling via glycogen accumulation in protein or lipid-associated complexes. These glycogen storage cardiomyopathies are described earlier in this chapter.

**47.3.5.6 Alterations in Intracellular Calcium Cycling.** Increasing evidence points to the importance of appropriate myocyte calcium homeostasis, which, if altered, may be a common and basic mechanism for heart failure. Abnormalities in the transcription and translation of important modulators of  $\text{Ca}^{2+}$  have been associated with both acquired and inherited cardiomyopathies and models of heart failure (Figure 47-16). Excitation–contraction coupling is the fundamental mechanism linking electrical signaling to the mechanical work of myocytes and is reviewed earlier in this chapter. Key mediators of this process are troponin–actin interactions, ryanodine receptors (RyR2) channels triggering calcium-induced calcium release from the SR), and the SR  $\text{Ca}^{2+}$ -ATPase pump (SERCA2a, which triggers relaxation and  $\text{Ca}^{2+}$  reuptake into the SR as modulated by phospholamban).

**47.3.5.6.1 Phospholamban.** Mutations in phospholamban are rare causes of familial DCM and heart failure (195,196). Biochemical studies on human specimens suggest that both chronically enhanced and decreased phospholamban activity have detrimental effects on cardiac function (195,197).

**47.3.5.7 Other DCM Genes.** Additional gene mutations have been demonstrated to cause DCM through unknown mechanisms. Mutations in ABCC9 encoding SUR2A, a regulatory subunit of the ATP-sensitive potassium channel ( $\text{K}_{\text{ATP}}$ ), have been identified in idiopathic DCM. Recent study reports missense and frameshift mutations in ABCC9, leading to defective catalysis-mediated pore regulation and resulting in DCM (198).

Dominant mutations in heart shock protein co-chaperone BCL2-associated athanogene 3 (BAG3) cause familial DCM (199). In addition, a nonsynonymous SNP located within the coding sequencing of BAG3 has been associated with sporadic cases of DCM (200).

Mutations in G4.5 (tafazzin), an X chromosome-encoded acyltransferase protein of unknown function,

**FIGURE 47-16** Mutations in proteins involved in intracellular calcium cycling cause cardiac remodeling (DCM, HCM, ARVD) and heart failure. Intracellular  $\text{Ca}^{2+}$  trafficking coordinates excitation–contraction coupling and myocyte contraction and relaxation. Calcium entry through transmembrane L-type calcium channels triggers a larger amount of calcium-induced calcium release (CICR) from the SR reservoir through the ryanodine receptor (RyR2), as regulated by calstabin2 and calsequestrin2. Sarcomere contraction then occurs. Relaxation occurs with  $\text{Ca}^{2+}$  reuptake into the SR via sarcoplasmic/endoplasmic calcium ATPase (SERCA2a), modulated by phospholamban. These molecules are regulated in a dynamic fashion by PKA-mediated phosphorylation.  $\text{Ca}^{2+}$  is also involved in other intracellular cascades, including calcium-calmodulin. (Reproduced from Morita, H.; Seidman, J.; Seidman, C. E. *Genetic Causes of Human Heart Failure*. J. Clin. Invest. **2005**, 115, 518–526, with permission of The American Society for Clinical Investigation.)

give rise to Barth syndrome, an X-linked cardioskeletal myopathy and triad of DCM, neutropenia, and 3-methylglutaconicaciduria in infants (201). Mutations in cardiac sodium channel (SCN5A), a known genetic defect of Brugada syndrome and long QT syndrome type III, can cause DCM with conduction system disease (177,202,203).

### 47.3.6 Animal Models of DCM

Mouse models of mutations represented in human DCM assist in the investigation of the consequences of these mutations as well as in the identification of important downstream pathways. Mice that carry myosin mutations that cause human DCM develop morphological and functional characteristics of DCM. Isolated myocytes from these mice exhibit depressed contractile function and reduced capacity to translocate actin, biophysical deficits that are the opposite of those that occur with HCM mutations (157,204). Remarkably, mice that carry two copies of dominant human HCM mutations (in myosin heavy chain or in MyBPC) develop DCM, heart failure and a predisposition for premature death (118,205–207). That mutant gene dosage can convert HCM to DCM may indicate a critical threshold effect of

sarcomere dysfunction, beyond which decompensation and myocyte death occurs.

Mouse gene mutations in the muscle LIM protein (208), desmin (209), and  $\delta$ -sarcoglycan (210) indicate that dysfunction of different elements of the cytoskeleton plays a causal role in the development of the DCM phenotype. Signals that ensue from these deficits that remodel the heart remain unknown.

There are inherent limitations in extrapolating results derived from mouse models to human pathophysiology. Mice null for  $\delta$ -sarcoglycan develop coronary artery spasm with eventual development of DCM related to multiple prior myocardial infarctions and myocyte necrosis (211). Administration of the L-type calcium channel blocker, verapamil, diminishes spasm and improves cardiac function. In contrast, human DCM associated with  $\delta$ -sarcoglycan mutations are thought to result in a deleterious dominant-negative effect on the dystrophin–sarcoglycan complex. Coronary artery abnormalities have not been described (176).

The molecular mechanisms of one pathogenic phospholamban mutation have been investigated via development of a transgenic mouse model of the Arg9Cys mutation (195). Biochemical studies suggested the presence of abnormal protein kinase A interactions that

inhibited the phosphorylation of mutant and wild-type phospholamban. This is predicted to result in the constitutive inhibition of SERCA2a due to excessive phospholamban activity. Indeed, mutant mice showed prolonged calcium transients, delayed myocyte relaxation, and decreased responsiveness to  $\beta$ -adrenergic stimulation. At the organ level, transgenic mice developed marked biventricular cardiac dilation and heart failure.

In addition to studying the effects of introducing mutations into the mouse genome, functional insights have been gained by studying the ability of other genetic manipulations to complement or rescue phenotype. For example, knocking out the muscle LIM protein (MLP) in mice causes neonatal DCM (208). If these MLP mice are crossed with mice lacking phospholamban, normal cardiac function results (197). Phospholamban functions to inhibit SERCA2a, an ATPase responsible for reuptake of calcium into the SR during myocyte relaxation. The observation that phospholamban inhibition leads to functional improvement of hearts genetically predisposed to the development of heart failure highlights the fundamental importance of intracellular calcium handling in pathways of heart failure and suggests potential novel treatment strategies.

Studies of lamin A/C mutations in mice show markedly elongated and dysmorphic nuclear architecture, fragmentation of heterochromatin, and defects in mechanotransduction (190,212,213). Myocytes carrying lamin A/C mutations have poor myocyte viability and are histologically similar to myocytes with mutations in desmosome proteins. This has led to speculation that lamins may serve as myocyte mechanosensors (155). Heterozygous lamin A/C mutations (LMNA<sup>+/-</sup>) in mice reduce cardiac lamin levels and predominantly induce early-onset apoptosis in electrically active myocytes and progressive electrophysiologic disease. Ultimately, nonconducting ventricular myocytes of LMNA<sup>+/-</sup> hearts succumb to diminished lamin levels resulting in late-onset DCM and heart failure, which presumably arise independently from electrophysiologic deficits (190).

Using genome-wide expression profiling in hearts from mice carrying a LMNA missense mutation led to the identification of activation of mitogen-activated protein kinase (MAPK) pathways that preceded clinically detectable DCM (186). Pharmacological treatment of LMNA mutant mice with ERK or JNK inhibitors after the onset of cardiac phenotypes prevents LV end-systolic dilation, increases cardiac ejection fraction, and reduces cardiac fibrosis. These findings suggest that inhibitors of ERK and JNK inhibitors may potentially benefit human patients with LMNA cardiomyopathy.

### 47.3.7 Diagnosis

DCM is a heterogeneous entity characterized by considerable genetic and clinical heterogeneity, a multitude of different molecular pathways, and a relatively low

prevalence of specific mutation types. The diagnosis of DCM is based on clinical evaluation and the finding of dilated cardiac chambers with only modest hypertrophy. There is great variability both in the degree of systolic dysfunction and the presence of associated phenotypes. As described earlier, these associated phenotypes may be cardiac (conduction system disease, arrhythmias, valvular abnormalities, congenital defects) or noncardiac (affecting skeletal muscle, metabolic pathways, and neurologic function). A careful and detailed family history should be obtained in all presenting individuals with a low threshold to perform systematic family clinical screening to assess for the presence of genetic disease. Individuals who are identified to have asymptomatic left ventricular dysfunction and/or enlargement should be followed closely and treated aggressively to attempt to prolong the asymptomatic phase and abrogate the development of a more profound phenotype. Recent availability of clinical genetic testing at many molecular diagnostic laboratories is listed at the National Center for Biotechnology Information Gene Tests Website (*Gene Tests* website). Incorporation of next-generation sequencing technology into clinical molecular genetic screening will facilitate the identification of variants in DCM and substantially improve the detection rate of pathogenic mutations.

### 47.3.8 Management

The management of genetic DCM follows management strategies of all-cause heart failure. Over the past decade, there have been significant strides in the management of systolic dysfunction heart failure. Standard medical regimens have been developed that have been shown to improve the morbidity and mortality of heart failure patients (reviewed in Reference (214)). Strategies incorporate neurohormonal inhibition [angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers combined with beta-adrenergic blockade and, when appropriate, mineralocorticoid antagonism], diuresis to reduce systemic and pulmonary venous congestion, and optimization of heart rate, rhythm, and blood pressure. Medically refractory heart failure may be addressed with novel surgical and mechanical therapies, including cardiac resynchronization therapy (biventricular pacing), valve repair/replacement, ventricular reconstruction surgery, and mechanical cardiac assist. Patients with asymptomatic left ventricular dysfunction have also been shown to benefit from early medical intervention, particularly early initiation of ACE inhibitors (215). This highlights the need for early detection of disease by routine and systematic evaluation of family members.

## 47.4 ATYPICAL CARDIOMYOPATHIES

A genetic etiology has also been described in less common forms of cardiomyopathy, including arrhythmogenic

right ventricular dysplasia (ARVD), restrictive cardiomyopathy, and ventricular noncompaction. Knowledge of molecular mechanisms in these rare types of cardiac disease is considerably less sophisticated than in more commonly encountered forms of hypertrophic and DCMs.

## 47.4.1 Arrhythmogenic Right Ventricular Dysplasia

**47.4.1.1 Prevalence.** Originally described in 1977, ARVD is an inherited form of cardiomyopathy, also known as arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) (216). The prevalence is unclear, but estimated at 1/5000 (217–219). ARVD has been cited as the leading cause of sudden death in competitive athletes in Italy (220). Thirty percent of cases are thought to be familial, typically with autosomal dominant inheritance.

**47.4.1.2 Phenotype and Natural History.** In addition to the characteristic morphologic changes to the right ventricle, ARVD is associated with cardiac arrhythmias and an increased risk of sudden cardiac death. The risk of sudden death is notable, occurring at a rate of ~2.5% per year and accounting for ~20% of sudden deaths in athletes and individuals <35 years of age (220). Sick sinus syndrome and complete atrioventricular conduction block are late manifestations. Heart failure may also occur in ~20% of cases (38).

## 47.4.2 Pathology

ARVD is characterized by necrotic and/or apoptotic myocyte loss and fibrofatty replacement of the myocardium. The right ventricle is typically predominantly affected, although there may also be involvement of the left ventricle (220).

## 47.4.3 Genetics

**47.4.3.1 Cardiac Desmosomes.** Dominant mutations have been identified in genes encoding protein components of the desmosomes: plakoglobin (JUP), desmoplakin (DSP), desmocollin-2 (DSC2), desmoglein-2 (DSG2) and plakophilin-2 (PKP2) (221–225). Approximately 50% of ARVD patients are found to carry a mutation in one of these genes (226), with ~20–30% occurring in PKP2 (reviewed in Refs (227,228)). However, some symptomatic individuals of ARVD harbor homozygous or compound heterozygous mutations. A rare autosomal recessive form of ARVD is present in Naxos syndrome with associated clinical features of nonepidermolytic palmoplantar keratoderma and woolly hair. Distinct mutations in the plakoglobin and desmoplakin genes have been associated with this syndrome (229,230). Proteins implicated in ARVD are components of desmosomes and adherens junctions, therefore likely playing a role in cell-cell communication and transmission of force.

**47.4.3.2 Atypical ARVD Genes.** A mutation in the RYR2, which encodes the cardiac ryanodine receptor was initially identified as a cause of ARVD (231). More commonly, RYR2 mutations produce catecholeminergic polymorphic ventricular tachycardia (CPMVT), a rare genetic disorder characterized by sudden cardiac death during physical or emotional stress despite the presence of apparently normal cardiac morphology (232,233). The cardiac ryanodine receptor is located with the SR and is involved with calcium-induced calcium-release in response to the initial action potential triggered influx of calcium via L-type channels.

Mutations in the untranslated regions of TGF- $\beta$ 3 have been reported to cause ARVD in one family and unrelated ARVD patients (234).

A founding mutation in the gene encoding transmembrane protein 43 (TMEM43) caused ARVD that exhibited gender-related lethality. The median life expectancy in affected men was 41 years compared with 71 years in affected women. Heart failure was a late-onset consequence in survivors (235).

Four other chromosomal loci have been linked to familial ARVD, including chromosome 14q12–22 (219), 2q32 (219), 10p12–14 (236) and 10q22 (237,238).

## 47.4.4 Diagnosis and Management

Making the clinical diagnosis of ARVD is often difficult due to the variability of morphologic findings and technical difficulties in imaging the right ventricular myocardium. Echocardiography and cardiac MRI studies are typically used to assess right ventricular size and function (Figure 47-17). ARVD is suggested by the presence of an enlarged, oftentimes dysfunctional right ventricle. MRI may be better able to assess for the presence of fatty infiltration into the RV wall.

Standard medical therapy with ACE inhibition,  $\beta$ -adrenergic blockade, and diuresis is indicated for

**FIGURE 47-17** Cardiac MRI images of a patient with ARVD. Four-chamber black-blood fast-spin echo sequence demonstrates high signal intensity in the epicardial aspects of the right ventricular free wall suggestive of fatty infiltration of the right ventricle and matching the regional RV dysfunction seen on cine imaging. (Courtesy of Raymond Kwong, MD, Cardiovascular Division, Brigham and Women's Hospital, Boston, MA.)

symptomatic heart failure. Because of the increased risk of ventricular tachyarrhythmias and sudden death, ambulatory EKG monitoring should be performed at regular intervals. Patients at higher risk for sudden death on the basis of symptoms (syncope, ventricular ectopic activity) or family history should be considered for prophylactic implantable cardioverter defibrillator (ICD) placement. Clinical screening of first-degree relatives is also recommended. Comprehensive DNA sequence analysis of the known ARVD-associated genes currently identifies a causative mutation in ~50% of ARVD probands (227). Clinical molecular genetic testing for ARVD is presently provided at several molecular diagnostic centers in the US (*Gene Tests* website). Genetic counseling is also recommended for individuals with ARVD and their relatives.

### 47.4.5 Ventricular Noncompaction

Noncompaction of the ventricular myocardium is a poorly understood cardiomyopathy thought to be caused by failure of the spongiform myocardium to fully compact during embryonic development. This results in a highly trabeculated appearance of the ventricular myocardium, particularly at the apex. It is also known as LVNC, spongy myocardium or left ventricular hypertrabeculation.

**47.4.5.1 Prevalence.** The largest case series of ventricular noncompaction suggests a prevalence of 0.014% of patients referred for echocardiography (239). A male predominance of 56–82% has been reported (239–241). Patients typically present in childhood or early adulthood, but the age at presentation has been quite variable.

**47.4.5.2 Phenotype and Natural History.** In the early stages of embryogenesis, the myocardium is organized in a loose network of fibers with deep crevices separating the myocardium from the left ventricular cavity. A process of compaction of this spongy tissue occurs between 5 and 8 weeks of development resulting in a densely trabeculated myocardium. This is coincident with the development of the coronary circulation (242). Isolated ventricular noncompaction was first described in 1990 and characterized as persistence of embryonic myocardial morphology in the absence of coexisting cardiac anomalies (243). The left ventricle is universally affected; right ventricular involvement is present in <50% of cases (241,242). The clinical course may be marked by heart failure, dysrhythmias, and an increased risk of thromboembolic events. There is also an association with neuromuscular disorders and facial dysmorphism in children (239,241).

Although LV systolic function may be preserved, the majority of patients in reported series have had symptomatic heart failure and impaired systolic and diastolic function. Cardiac arrhythmias also occur commonly, including atrial fibrillation, ventricular tachyarrhythmias, supraventricular tachycardia, and heart block. Ventricular tachyarrhythmias may be present in >40% of patients and sudden cardiac death may account for half of patient deaths (239,242,243).

An increased risk of thromboembolic events to the cerebrovascular, pulmonary, and mesenteric circulations has been associated with noncompaction with estimates of incidence ranging from 21% to 38% (242). The mechanism is unclear, but may be related to an increased predisposition to left ventricular thrombus formation due to extensive trabeculations and decreased systolic function as well as superimposed atrial fibrillation in a subset of patients. One series of pediatric patients with noncompaction reported no systemic embolic events, suggesting that the risk increases with increasing age (244).

Information on prognosis is variable and remains a work in progress. Initial studies suggested a severe prognosis with a 60% incidence of death or cardiac transplantation within 6 years of diagnosis (241). The prognosis appears less severe in the pediatric population with a lower incidence of thromboembolic events, ventricular tachyarrhythmias, and premature death (244). There is likely a spectrum of findings and earlier observations may be confounded by referral bias. Higher risk features have been suggested, including larger presenting left ventricular end-diastolic diameter, NYHA class III to IV heart failure symptoms, atrial fibrillation, and bundle branch block. These features were more frequently documented in nonsurvivors than survivors, and such patients should be considered for more pro-active and pre-emptive treatment, including ICD implantation and evaluation for cardiac transplantation (239).

### 47.4.6 Pathology

Histologically, isolated ventricular noncompaction differs from noncompaction seen in association with congenital heart disease in that there is communication between the intertrabecular recesses and the LV cavity in the former and both the LV cavity and the coronary circulation in the latter (239,242). There are no pathognomonic histologic findings, although increased interstitial fibrosis has been described. Necrotic myocytes has been observed within the prominent trabeculations of individuals with noncompaction.

### 47.4.7 Genetics

Both sporadic and familial types of isolated ventricular noncompaction have been reported. The initial study of isolated ventricular noncompaction, which mainly involved children, reports familial recurrence in ~50% of patients (243). However, the largest report of adult cohort with isolated noncompaction describes both sporadic and familial forms with a familial incidence roughly approximated at 18% (244). As compared with the initial report, the lower percentage of familial recurrence could be contributed to incomplete screening of siblings (242).

The search for genes responsible for isolated ventricular noncompaction remains a work in progress. Gene mutations have not yet been identified for sporadic disease. To date, ventricular noncompaction has been reported in several patients with mitochondrial disorders. However, only a few causative mutations, e.g. mtDNA 3243A>G and 8381A>G, have been reported in such patients (245).

**47.4.7.1 G4.5.** This gene encodes a novel protein family, tafazzins. Family with X-linked ventricular noncompaction was found to have a mutation in this gene in a region of the X chromosome (Xq28) where linkage has been identified in other cardiomyopathic syndromes, including Barth syndrome, myotubular myopathy, and muscular dystrophies (246,247). No mutations in G4.5 were identified in noncompaction individuals associated with congenital heart disease. To date, mutations in G4.5 have been predominantly reported in young male patients rather than adult patients.

**47.4.7.2 LDB3.** Mutations in the cypher/ZASP/LDB3 gene on chromosome 10q23.2 encoding for an LIM-binding protein, a component of the Z-line in both cardiac and skeletal muscles (182,248), cause myofibrillar myopathy or isolated cardiomyopathy. Also, it has been reported as a pathogenesis for both DCM with or without isolated ventricular noncompaction, linking this gene defect to left ventricular dysfunction and dilation (182).

**47.4.7.3 LMNA.** Recent study reported one LMNA mutation (Arg190Trp) in a DCM patient with features of ventricular noncompaction, suggesting that noncompaction may be part of the clinical spectrum of laminopathies (249).

**47.4.7.4  $\alpha$ -dystrobrevin.** This gene is alternatively spliced and only expressed in the heart. Mutations in  $\alpha$ -dystrobrevin (DTNA) gene have been identified in noncompaction individuals associated with congenital heart disease (240). Furthermore, mutations in DTNA have been demonstrated to result in muscular dystrophy in humans as well as skeletal myopathy and cardiomyopathy in mouse models (250).

**47.4.7.5 NKX2.5.** One cardiac-specific homeobox gene, NKX2.5, has also been suggested as a candidate gene

due to the finding of noncompaction in a child with a deletion of chromosome 5q where the gene is encoded (251).

**47.4.7.6 Sarcomere Proteins.** Mutations in some cardiac sarcomere genes (ACTC1, MYH7, MYBPC3, and TNNT2) have been associated with ventricular noncompaction with either traditionally described DCM or HCM. To date, ACTC1 (20%) and MYH7 (22%) appear to be sarcomere genes frequently found in association with ventricular compaction (252).

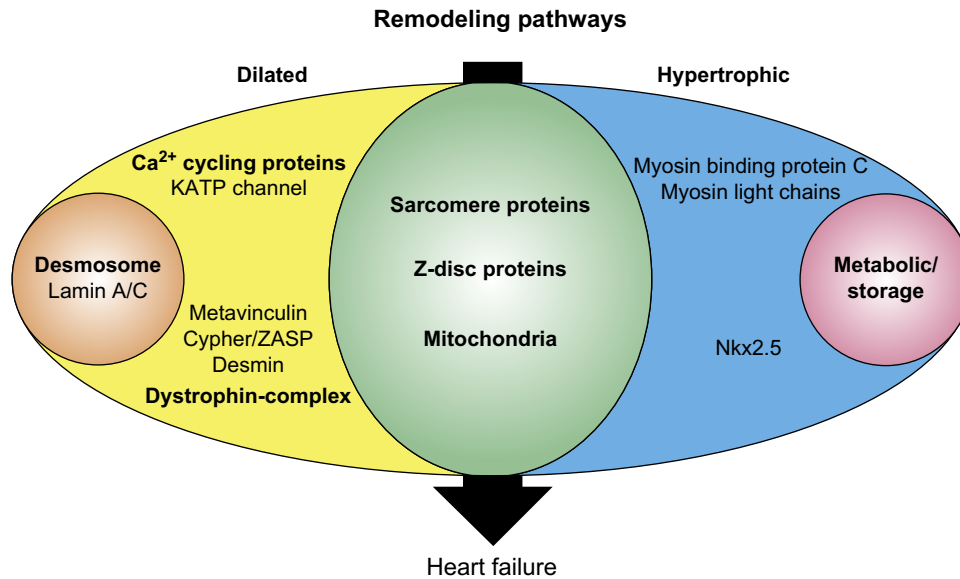

## 47.4.8 Diagnosis and Management

Ventricular noncompaction is typically diagnosed based on echocardiographic findings of multiple prominent ventricular trabeculations with multiple deep intertrabecular recesses. Color flow Doppler imaging can help to demonstrate communication of blood flow into these intertrabecular recesses (Figure 47-18). A two-layered endomyocardium with an increased ratio of noncompacted to compacted thickness at end systole is suggestive. (>1.4 in children or infants and >2.0 in adults; Reference (252)). The left ventricular apex is most commonly affected. LV systolic function is variable. Earlier reports suggested that decreased ejection fraction was ubiquitous, but there is clearly a spectrum of functional defects ranging from normal to severely impaired. Alternate imaging modalities including left ventriculography, computed tomography, and cardiac MRI may also assist in resolving ventricular morphology.

Management consists of standard medical therapy for functional abnormalities (e.g. symptomatic heart failure or asymptomatic LV systolic dysfunction). Because of the increased risk of associated comorbidities including atrial fibrillation, ventricular tachyarrhythmias, and sudden death, ambulatory EKG monitoring should be performed at regular intervals. ICD placement should be considered for patients at higher risk for sudden death based on findings on ambulatory monitoring, symptoms, syncopal episodes or a family history of sudden death. Systemic anticoagulation should also be considered and is mandatory if atrial fibrillation is identified. Aspirin

**FIGURE 47-18** Echocardiographic images from a patient with isolated ventricular noncompaction. Note the spongy appearance of the myocardium with prominent apical trabeculations interspersed with deep recesses (left). Color flow Doppler imaging (right) can highlight the blood flow interdigitating between the trabeculations.

**FIGURE 47-19** Human gene mutations can cause cardiac hypertrophy (blue), dilation (yellow), or both (green). Pathways that lead to pathologic remodeling of the heart involve force generation and transmission (sarcomere proteins and cytoskeletal elements), energy production and regulation [metabolic/glycogen storage proteins (pink) and mitochondrial proteins], and intracellular calcium cycling (sarcomere proteins, Ca<sup>2+</sup>-cycling proteins). (Reproduced with permission from Morita, H.; Seidman, J.; Seidman, C. E. *Genetic Causes of Human Heart Failure*. J. Clin. Invest. **2005**, 115, 518–526.)

may be administered for reducing the risk of systemic embolism in patients with isolated ventricular noncompaction. Clinical screening of first-degree relatives is also recommended. Clinical molecular genetic testing for isolated ventricular noncompaction-associated genes is currently available (*Gene Tests* website). Genetic counseling is also recommended for affected individuals and their family members.

## 47.5 CONCLUSION

Unraveling the molecular and genetic basis of inherited cardiomyopathies will provide further insight into their fundamental pathophysiology. The study of gene mutations associated with structural heart disease has been instrumental in the identification of key pathways involved in the development of abnormal cardiac morphology, including deficits in force transmission and generation (elements of the sarcomere apparatus and cytoskeleton), energy production and regulation (mitochondrial, metabolic, and glucose storage genes), and intracellular calcium handling (sarcomere and Ca<sup>2+</sup>-cycling proteins) (Figure 47-19). This information will lead to better understanding of the mechanisms underlying cardiac development and the more common forms of acquired dilated and hypertrophic heart disease. Knowledge gleaned from progress in the basic science arena will ultimately be translated into clinical practice. For example, screening of family members in DCM kindreds may identify individuals with asymptomatic left ventricular dysfunction or dilatation. Early initiation of medical therapy at this stage improves symptoms, morbidity, and prognosis. Genetic identification and biomarker

detection of individuals carrying gene mutations associated with HCM prior to the development of overt clinical disease provides a critical opportunity to intervene to alter phenotypic development rather than relying on the contemporary and suboptimal strategy of symptom palliation. Whole genome next-generation sequencing technologies would enable high-throughput investigation of the roles of genetic modifiers in HCM with atypical clinical expression. More definitive treatment to interrupt the natural history of dilated and hypertrophic cardiomyopathies will be drawn from better mechanistic understanding of how inherited gene defects remodel the heart.

### Biographies

**Polakit Teekakirikul** received his medical degree from Chulalongkorn University and his clinical pathology training at Siriraj Hospital and Mahidol University in Thailand. He completed his fellowship in clinical molecular genetics at Harvard Medical School. He is doing his research fellowship in genetics in the laboratory of Drs Christine and Jonathan Seidman at Harvard Medical School and Brigham and Women's Hospital. His research interest is in molecular genetics of inherited cardiomyopathies.

**Carolyn Ho** is an Assistant Professor of Medicine at Harvard Medical School and Medical Director of the Cardiovascular Genetics Center at Brigham and Women's Hospital. Dr Ho obtained her undergraduate degree from Yale University and her medical degree from Harvard Medical School. She trained at Brigham and Women's Hospital for both Internal Medicine residency and Cardiology fellowship before joining the staff of the Cardiovascular Division in 2001. Dr Ho's research focuses on developing clinical translational studies—using genetics to characterize early phenotypes and to design new treatment paradigms to change the natural history of inherited cardiomyopathies.

**Christine Seidman** is the Thomas W Smith Professor of Medicine and Genetics at Brigham and Women's Hospital and Harvard Medical School. She is an Investigator of the Howard Hughes Medical Institute, and a member of Institute of Medicine and the National Academy of Science. Dr Seidman received her MD from George Washington University School of Medicine, completed residency at Johns Hopkins Hospital and received subspecialty cardiovascular training at the Massachusetts General Hospital. At the Brigham and Women's Hospital she directs the Cardiovascular Genetics Center. Dr Seidman's research focuses on discovery of the genetic basis for human disease, in particular those affecting the heart. Complementing these human genetic studies, her laboratory performs basic investigations to elucidate pathogenetic mechanisms and to harness this information to explore novel therapeutics.

### 48.1 HISTORICAL PERSPECTIVES AND INTRODUCTION

Heritable and idiopathic pulmonary arterial hypertension (PAH), together formerly known as primary pulmonary hypertension (PPH; OMIM 178600), are clinically identical progressive disorders characterized by elevated pulmonary artery pressure with pathologic changes originating in the precapillary pulmonary arteries. Characteristic pathologic changes were described in autopsy specimens as early as 1891 by Romberg but the disease was not reliably diagnosed clinically until the development of cardiac catheterization. The term *primary pulmonary hypertension* was coined in 1951 to describe what we now recognize as PAH, with the first clinical description of the disease by Dresdale et al. (1). The term PPH was used exclusively for fifty years and typically referred to those with either familial or sporadic precapillary pulmonary hypertension. The 2003 World Congress on PAH changed the nomenclature from PPH to familial PAH (FPAH) for patients with the disease and either a positive family history or a PAH-associated gene mutation, and idiopathic PAH (IPAH) for those patients who have neither. *BMPR2* is the gene encoding bone morphogenetic protein receptor type II (*BMPR2*; OMIM 600799), which is mutated in over 75% of families with PAH. The

discovery of the *BMPR2* gene's association with PAH, as well as the rare occurrence of mutations in other members of the transforming growth factor  $\beta$  (TGF $\beta$ ) superfamily of receptors with PAH (*ACVRL1* and *ENG*), prompted a revision of nomenclature at the 2008 World Congress on PAH: patients with either a family history of PAH or a detectable mutation in an associated gene are now considered to have heritable PAH (HPAH), whereas patients with neither have sporadic PAH known as IPAH (2).

PAH is defined clinically by the presence of pulmonary hypertension in the absence of known secondary causes such as lung disease, heart disease, and thromboembolism. As with its initial epidemiologic descriptions, PAH affects females more than twice as often as males and occurs at all ages although whether severity is gender-specific remains in debate. Before disease-specific therapy was identified in the mid-1990s starting with intravenous epoprostenol, the disease characteristically progressed to right heart failure and death in just a few years from the time of diagnosis. Now, several therapies specifically approved to treat PAH patients exist although whether any of these agents only improve functional status or also specifically increase survival is unclear. However, with vital new understanding about the basic pathogenesis and novel treatment regimen trials now in progress, the outlook for PAH patients is more hopeful than ever before.

## 48.2 NOMENCLATURE

PAH was previously known as PPH although this label no longer exists. Several classification schemes have been used to characterize PAH since its initial descriptions in the 1950s as PPH by Dresdale et al. (1). The currently accepted system was established at the most recent World Symposium on Pulmonary Hypertension in 2008 (Dana Point, CA, USA). Group 1 pulmonary hypertension, known as PAH, includes PAH that occurs both in families and as a sporadic disease (Table 48-1). In recognition of genetic advances in understanding, including the discovery that mutations in selected genes occur among patients without family history of PAH previously felt to have sporadic disease, patients with PAH are labeled HPAH if they possess a family history of PAH and/or a detectable mutation in a PAH-associated gene. Those subjects who would otherwise meet criteria for what is classically considered PPH but lack family history or detectable mutation are considered to have the sporadic disease IPAH. It is likely that as our genetic understanding evolves and detection methods improve, the distinction between HPAH and IPAH will further narrow, but that remains to be seen.

## 48.3 INCIDENCE AND PREVALENCE OF HPAH AND IPAH

Current prevalence estimates of PAH due to HPAH and IPAH causes probably underrepresent the burden of

disease because of a number of factors, including recognition and diagnosis of disease as well as disease classification (3). However, current conservative estimates suggest approximately 6–15 cases per million in North America and Europe. It has generally been accepted that owing to the intervention of new pharmacologic agents, the prevalence of disease is increasing although this has not been proven. The number of new cases of IPAH or HPAH (incident cases) is estimated to be 1–2 per million population per year in North America and Europe. Insufficient information is available to determine whether specific populations have different frequencies of PAH although reports from groups of different ancestries are beginning to emerge. For example, it is clear that among Chinese and Japanese patients, as with those of European descent, *BMPT2* mutations are detectable in both HPAH families and IPAH patients. However, the exact prevalence is unknown as full sequencing augmented by multiplex ligation-dependent probe amplification or other assays to detect large deletions and duplications have not been performed in large patient cohorts (4,5).

## 48.4 PHENOTYPE AND NATURAL HISTORY OF HPAH AND IPAH

PAH is characterized by widespread obstruction or obliteration of the smallest pulmonary arteries (6). These arteries are obstructed by changes in all the layers of the vascular wall, including smooth muscle hypertrophy in the vascular media, obstruction of the lumen by concentric intimal fibrosis and microthrombi, and changes in the surrounding adventitia as well (7,8). When a sufficient number of vessels are occluded, the resistance to blood flow through the lungs increases. In order to maintain adequate pulmonary blood flow, the right ventricle compensates by generating higher pressure. The early phase of disease results in few or no symptoms until the right ventricle can no longer compensate for the increased resistance, and then progressive heart failure ensues. Initial symptoms include dyspnea, fatigue, chest pain, palpitation, syncope, or edema (9). Individuals who have HPAH have identical symptoms, signs, and clinical course as those with IPAH (9). The discovery of mutations in *BMPT2* as the major genetic association provided the first real understanding of the central pathogenesis and provided a basis for genetic testing (10,11), as well as the potential for new and innovative future therapies to address the basic pathogenesis at the molecular level. However, to date, the exact mechanism by which *BMPT2* gene mutations increase the susceptibility to PAH has not been elucidated and is a focus of intense investigation.

PAH affects individuals of all ages, including the very young and the elderly. While females are more than twice as likely to be affected as males, historically, the severity and outcome of disease have not appeared to vary according to gender. However, recent epidemiologic data

**TABLE 48-1 Pulmonary Hypertension (PH), Clinical Classification**

Group 1 PH: Pulmonary Arterial Hypertension (PAH):
<b>Idiopathic PAH</b>
No known associated gene mutation and no family history of PAH
<b>Heritable PAH</b>
Possess a genetic mutation known to associate with PAH (e.g. <i>BMPT2</i> , <i>ALK1</i> , <i>ENG</i> )
Subject in a family with documented PAH, but no detectable gene mutation of relevance
<b>PAH associated with drug or toxin use (e.g. fenfluramine exposure)</b>
<b>PAH associated with other disease states</b>
Connective tissue diseases
HIV
Portal hypertension
Congenital heart disease
Schistosomiasis
Chronic hemolytic anemia
<b>Persistent pulmonary hypertension of the newborn</b>
Group 1' PH: pulmonary veno-occlusive disease (PVOD); pulmonary capillary hemangiomatosis (PCH)
Group 2 PH: presence of left heart disease
Group 3 PH: presence of lung disease and/or hypoxia
Group 4 PH: chronic thromboembolic PH (CTEPH)
Group 5 PH: less-distinct and likely multifactorial mechanisms

Adapted from Simonneau et al., JACC 2009 Jun 30, 54 (Suppl. 1), S43–S54.

does suggest that while more likely to develop disease, among subjects with PAH, females may have improved survival, especially when compared to older males. In HPAH, mortality occurs at all ages regardless of gender, and we find that 20% of patients died before age 20, and 20% died after age 50 (Figure 48-1) (12). The clinical characteristics and natural history of untreated PAH (then known as PPH) were reported in a multicenter study (9), which was conducted before the identification of the first widely effective therapies. This study included 194 affected individuals from 32 US centers, where other causes of pulmonary hypertension were rigorously excluded. The mean age at diagnosis was 36 years, and while the clinical course varied, most untreated individuals gradually deteriorated with an overall mean survival of only 2.8 years. Preceding the availability of effective therapy, the clinical functional capacity correlated very closely with survival. Patients who were New York Heart Association (NYHA) class IV had a mean survival of 6 months, whereas those who were class III had a mean survival of 2.5 years, and those who were class I or II had a mean survival of 5 years (13). Family history was positive for only 6% of cases in that initial report although the method of acquisition of family history was not uniform across the cases reported.

## 48.5 INHERITANCE AND GENETICS OF PAH IN FAMILIES

PAH can occur as a sporadic (idiopathic, IPAH) disease or present among subjects within families (heritable, HPAH) known to possess PAH risk. Regardless, these two disorders are clinically and histologically indistinguishable. PAH in families (now classified as HPAH) represents at least 6% of all cases (9) and displays an autosomal dominant mode of transmission with reduced penetrance and genetic anticipation (Figure 48-2) (14–16). Significantly reduced penetrance in most families likely confounds the recognition that the disease is familial, and not uncommonly, a subject initially assigned the diagnosis of sporadic IPAH will possess a detectable *BMPR2* mutation—the diagnosis then changes to HPAH (40).

**FIGURE 48-1** Cumulative mortality of patients with HPAH in families. Circles represent females; squares represent males.

In fact, heterogenous germline mutations in *BMPR2* have now been found in the majority of familial (>75% tested) (17) as well as about 15% of cases previously labeled IPAH (18–21). Irrespective of the family history, subjects with an identifiable germline mutation in *BMPR2* have heritable disease (HPAH) by definition (2).

*BMPR2* is a receptor within the TGF $\beta$  superfamily of receptors critical to cell signaling. The gene encoding *BMPR2* resides on chromosome 2q33 and produces multiple isoforms—the most common comprises all 13 exons (Figure 48-3). It is a large gene, spanning 182,965 bp. The receptor has four major domains (Figure 48-3), including an extracellular (exons 1 through 3), a transmembrane (exon 4), and an intracellular serine/threonine kinase (exons 5 through 11) domain and a large C-terminus tail (exons 12 and 13); the latter is not shared by other TGF $\beta$  receptors. Patients within families with PAH related to *BMPR2* mutations share the same mutation although most mutations differ across families. To date, over 300 mutations have been reported throughout the gene from patients with PAH (17). The reported *BMPR2* mutations are heterogenous, including frameshift, partial deletion, splice site, nonsense, and missense mutations (17). A large proportion of mutations presumably result in a haploinsufficiency of *BMPR2* although some mutations promote a dominant negative effect (22).

*BMPR2* mutations remain the most commonly identified genetic susceptibility for PAH (17). However, rare variations in three additional loci are associated with PAH. As with *BMPR2*, each of these is directly related to TGF $\beta$  receptor superfamily signaling. Located on chromosome 13, *SMAD9* (encodes Smad8) was found to be mutated in one patient with sporadic PAH (23) and its discovery makes sense given the importance of Smad signaling to PAH, although additional cases have yet to be reported. In a small percentage of cases, patients with hereditary hemorrhagic telangiectasia (HHT) develop PAH. HHT is a vascular dysplasia characterized by mucocutaneous telangiectasias, recurrent epistaxis, gastrointestinal bleeding, and arteriovenous malformations (AVMs) of multiple organs including the lungs. When PAH is present in HHT, it is clinically and histologically identical to HPAH and IPAH (24). However, in HHT, right heart failure is most often due to shunting through pulmonary AVMs and not PAH. Mutations in activin receptor-like kinase 1 (*ACVRL1*) located on chromosome 12 and endoglin (*ENG*) on chromosome 9 both associate with PAH and HHT although the great majority of patients have mutation in *ACVRL1* (25,26). Interestingly, *ACVRL1* and *ENG* encode proteins of the TGF $\beta$  superfamily of receptors. *BMPR2*, *ALK1* and *ENG* all signal intracellularly via the Smad family of coactivators (27,28). Similar to the *BMPR2*-associated HPAH, reduced penetrance and variable expressivity of PAH is seen in HHT (20,21).

All PAH-associated genes described to date, *BMPR2* being the most common, are mutated in the germline and

**FIGURE 48-2** Pedigree of a family with PAH and a detectable *BMPR2* gene mutation.

**FIGURE 48-3** Schematic diagram of *BMPR2* gene domains and mutations. Mutations have been described throughout this large gene.

are not specific to the lungs. These germline mutations have either been passed down through a family over time or occurred *de novo*, presumably in an oocyte or a spermatocyte. Regardless, the reduced penetrance of disease suggests the possibility that expression among susceptible subjects requires one or more additional “second

hits,” of which somatic changes in the lung are a possibility (29). In fact, small vessel obliteration due to exuberant cellular proliferation, evidence of endothelial cell monoclonality and somatic endothelial cell gene mutations, all are features that suggest PAH may be similar to an angioproliferative disorder with neoplastic features

(30–33). This prompted Aldred et al. to test the hypothesis that the acquisition of somatic mutations within the lung promotes the development of complex vascular lesions with neoplastic features. Interestingly, they demonstrated somatic chromosome abnormalities in the lung pulmonary artery endothelial cells of PAH patients, including one with a *BMPR2* mutation, as well as evidence of X chromosome loss and/or inactivation (34). While they documented somatic mutations in the endothelial cells of end-stage human PAH lungs, their findings require replication and further exploration before somatic changes are a widely accepted component of PAH pathogenesis (29).

The higher incidence and prevalence of HPAH among females compared to males is one of the many complicated and poorly understood factors involved in the inheritance and genetics of HPAH. HPAH also displays reduced penetrance within families and variable penetrance across families as well as genetic anticipation and variable expressivity.

### 48.5.1 Reduced Penetrance

*Penetrance* refers to the frequency with which a specific trait (phenotype) is expressed by individuals with a genotype known to be able to cause that trait. Owing to reduced penetrance, only about 20% of individuals with an HPAH-causing genetic mutation in *BMPR2* will develop detectable PAH during their lifetime. This characteristic of mutant *BMPR2* alleles suggests that possession of one mutant *BMPR2* allele is required but not sufficient to precipitate clinical expression of disease in most cases (32). To date, the mechanisms of reduced penetrance are unknown, and suggest a role for additional genetic and/or environmental modifiers of disease expression (33). For example, recent data suggest that the level of *BMPR2* gene expression by the wild-type allele may influence penetrance, with lower wild-type expression associated with higher penetrance (35). Epigenetic modification is an additional possible modifier of penetrance although it has been incompletely studied to date. No human is reported to have two *BMPR2* gene mutations, and animals genetically modified to lack the *BMPR2* gene do not survive embryonic development.

### 48.5.2 Gender Dimorphism

Aside from the presence of an identifiable mutation in a PAH-associated gene, gender is the most consistent determinant of HPAH expression. Females outnumber males  $\geq 2:1$  among both incident and prevalent cases of HPAH and IPAH. While not every family displays a strong gender bias, the vast majority are female predominant. The reasons for this disparity remain elusive. An increased incidence of HPAH among females suggests that either fewer males are successfully born to families with HPAH or females are more susceptible to having

detectable disease. On the basis of meticulous evaluation of our family pedigrees, we previously speculated that increased male fetal losses contributed to the gender discrepancy although this has not been independently validated (14). Alternatively, unclear genetic or hormonal factors may promote higher susceptibility for females relative to males. Reports from the French registry that the female/male ratio was identical in healthy *BMPR2* mutation carriers and noncarriers within PAH families suggested that the gender disequilibrium among PAH patients may result from specific gender-dependent factors such as hormones acting later in life rather than embryonic lethality or meiotic drive (16).

Interestingly, recent reports from the two large epidemiologic registries of PAH in France and in the United States found improved survival among females although it was unclear if this was due to effects on the pulmonary vasculature, heart or both (36,37). In addition, the survival disadvantage found in the United States study (REVEAL) was specific to men over age 60 years compared with younger men and compared with women at any age. Detailed prospective studies with validation will be necessary to fully appreciate the degree to which gender participates in survival if at all.

### 48.5.3 Variable Expressivity

The degree (mild to severe) to which rare genetic variation causes disease is not uniform among *BMPR2* mutation carriers, indicating variable expression of disease. For example, the age of onset and diagnosis among *BMPR2* mutants with PAH is highly variable, ranging from infancy to over 65 years of age (38). This variation is evident both within families (all affected subjects share the same *BMPR2* mutation) and across families (in most cases, different families have different *BMPR2* mutations). This again suggests that factors beyond the possession of a *BMPR2* mutation modify disease expression among susceptible subjects.

### 48.5.4 Genetic Anticipation

This refers to the increased severity or an earlier age of onset of disease for patients in subsequent generations in a pedigree. Initially perceived as predominantly a function of ascertainment bias, some evidence suggests that this truly occurs among families susceptible to PAH. While not uniform, the age at death in successive generations decreases consistently by about a decade in each generation among some families (14). However, this remains a finding in need of independent validation, and the concept is not without controversy since it lacks biological evidence of causation. However, progressively earlier ages of death continue to be a feature among our families with PAH, and recently were demonstrated by French researchers as well (39). This phenomenon is well described in several neurologic diseases, including fragile

X syndrome and Huntington disease. These neurodegenerative disorders associate with trinucleotide repeat expansions, which have not been identified in *BMPR2* or other PAH genes. While not reported in HPAH, progressive telomere shortening causes anticipation in autosomal dominant dyskeratosis congenita, which also associates with pulmonary fibrosis (40).

## 48.6 CONNECTING *BMPR2* TO PAH

Sufficient numbers of families with PAH (then known as PPH) were identified and DNAs were banked so that adequate power was available to conduct linkage analysis for a chromosomal location of a highly associated gene by the mid-1990s. In 1997, a microsatellite marker search established linkage to a 30-Mbp region on chromosome 2q33 (41,42).

### 48.6.1 Identification of Mutations in *BMPR2* in PAH That Occurs in Families

Because the sequence of the human genome had not been completed when the locus associated with PAH in families was mapped in 1997 and the critical interval for the familial locus was 30 Mbp (41), the subsequent search employed a candidate gene approach. Several genes with relevant functions, including those for an insulin-like growth factor and for neuropilin, a vascular endothelial growth factor receptor, were identified in the linkage peaks, but variations related to disease were not detected when DNAs of affected family members were analyzed. *BMPR2* was the third candidate studied, and it was selected on a functional basis because of its membership in the TGF $\beta$  family of receptors, which participate in the regulation of cell proliferation among many other roles.

We amplified exonic segments of *BMPR2* alleles from genomic DNAs of individuals with PPH and screened the amplicons for alterations by dideoxy fingerprinting, and found an altered pattern in a patient and healthy parent in one family (10). By DNA sequencing, we found that the change was a T deletion (2579–80 delT) that deleted a restriction site for *AseI* from this amplicon. We amplified the segment containing this mutation from DNAs of all available subjects in this family. The amplified segments were subjected to restriction endonuclease digestion, and the result was analyzed by agarose gel electrophoresis. These studies showed that, in this family, the 2579–80 delT mutation in *BMPR2* cosegregated faithfully and completely with the FPAH phenotype, greatly strengthening the evidence that the mutation was the real cause of the disease (10). In nearly the same time frame, another group independently reported FPAH linkage and the identification of *BMPR2* as the associated gene of interest (11).

Since the association of mutations in *BMPR2* with PAH, the majority of all families analyzed have been shown to possess a *BMPR2* mutation. In addition,

between 5% and 26% of cases of PAH thought to occur sporadically have also been found to associate with germline *BMPR2* mutations (4,19,43,44), with some documented cases of *de novo* mutations. The true frequency of mutations may yet be underestimated as the techniques employed in most of these studies may have failed to search for large gene deletions or rearrangements. Such mutations are well known to occur in PAH and may be missed by traditional sequencing techniques; in fact, advanced techniques that detect these mutations are now recommended for clinical testing for mutations among PAH patients (17,45,46).

### 48.6.2 Range of *BMPR2* Mutations

Within each FPAH kindred, every affected member has the same mutation, and only rarely do clearly unrelated kindreds share the same mutation. For example, our Vanderbilt HPAH cohort contains only a few truly unrelated families who share the same *BMPR2* mutation. The most common mutation among our families, and one of the few shared among families, is a nonsense mutation in the tail domain (exon 12; arginine to termination mutation at amino acid 899) (Figure 48-3). *BMPR2* is highly conserved in nature, and each amino acid substitution that results from the reported point mutations is predicted to alter receptor function. Mutations are equally divided among frameshift, nonsense, and missense, all predicted to alter the encoded transcript and result in a dysfunctional receptor. None of the mutations that are associated with PAH results in a receptor structure that would appear to be compatible with normal or increased function. Except for possible differences in penetrance across families, there are no other apparent differences, including gender, age of onset, and severity of disease, based on the location of mutations. However, owing to the rarity of mutations and heterogeneity, comprehensive studies of subjects lack sufficient power to explore effectively this question, and there are certainly families in whom the gender disequilibrium is more obvious than others.

### 48.6.3 *BMPR2* Mutations in PAH That Occurs Sporadically

Whereas HPAH is a complex genetic disease and there are no definitive influences on variable expression other than gender, in sporadic PAH, there are recognized environmental and biological triggers for disease, including associations with appetite suppressants (47), HIV infection (48), portal hypertension (49), and rheumatologic diseases (38,50). The best-documented environmental associations are aminorex, fenfluramine, and stimulants such as amphetamines (51). There is currently active study in the contribution of obesity, glucose intolerance, insulin resistance, and metabolic syndrome to sporadic PAH, and some data to suggest that many patients

struggle with these comorbidities—whether they are causative or simply associative is not yet clear (52–54). Studies are needed to examine the role of other factors, including hormone therapy, number of pregnancies, cigarette smoke, depression, systemic hypertension, altitude dwelling, diet, medications, lifestyles, and other potential modifying environmental influences on development of disease. These areas are now of great interest as presumably PAH develops because of the confluence of multiple factors that converge to promote disease among subjects with some form of underlying disease risk (12,34,54,55).

One such risk is the presence of a *BMPR2* gene mutation; however, among subjects with no prior family history, this is impossible to know before symptom onset. This was initially demonstrated by Thomson et al., who conducted a search for *BMPR2* mutations among 50 patients with “sporadic” PAH, in which the investigators sequenced the entire coding region and intron–exon boundaries of *BMPR2* (19). Germline mutations were found in 13 patients, each predicted to alter cell signaling response to ligands. While the precise prevalence of *BMPR2* mutations will require a comprehensive study of several hundred sporadic patients of varying ethnicities for whom family histories are well documented to be negative, it appears true that a proportion of sporadic PAH patients of multiple ethnic backgrounds possess a *BMPR2* mutation. These patients thus have heritable disease (HPAH), irrespective of family history. The several series published to date suggest that approximately 5–26% of patients with “sporadic” disease in fact have a *BMPR2* mutation (4,5,18–21,56). Our cohort at Vanderbilt represents a biased sample as we deeply probe family histories with our patients, and thus in our cohort, the percentage of “sporadic” patients with a *BMPR2* mutation is low (~6%) (22). As noted above, “sporadic” PAH patients with a *BMPR2* mutation are considered HPAH patients, while those without are classified as IPAH patients.

To determine whether *BMPR2* mutations occurred *de novo* in sporadic patients, or whether they were inherited, will require analysis of parental samples. There are many possible reasons why most “sporadic” PAH patients and a minority of HPAH kindreds do not yet have recognized *BMPR2* mutations. For example, the promoter, the intronic regions, and the large 3′ untranslated region of *BMPR2* in most sporadic studies were not examined. In fact, intronic mutations in *BMPR2* may be responsible for another 25% of familial cases that link to chromosome 2q33 (46). While it remains possible that rare variants in other primary genes associate with sporadic PAH, to date, no genes outside of the TGFβ receptor superfamily have been identified. Whole exome and whole genome sequencing, RNA sequencing, and other next generation genetic techniques provide novel platforms to evaluate more thoroughly this issue.

#### 48.6.4 *BMPR2* Mutations in Other Disorders

Other types of PAH have been studied for the presence of *BMPR2* mutations. One family with pulmonary veno-occlusive disease due to *BMPR2* mutation in exon 1 was described (58). In a cohort of 33 patients with PAH associated with fenfluramine ingestion, three had *BMPR2* mutations predicted to alter receptor function (21). Six individuals with congenital heart disease (complete type C atrioventricular canals, atrial septal defect, patent ductus arteriosus, partial anomalous pulmonary venous return, and aortopulmonary window with a ventricular septal defect) had responsible *BMPR2* variations (50).

*BMPR2* mutations were not found in 24 patients with PAH related to the scleroderma spectrum of disease (37). In addition, *BMPR2* mutations were not found in three studies of a total of 55 patients with HIV-related PAH (42). Importantly, *BMPR2* mutations that would be predicted to alter receptor function have not been found in any of 350 normal control subjects (not kin of subjects with PAH) reported to date.

#### 48.6.5 Additional Genetic Modifiers of IPAH and HPAH

While the search for rare variants associated with IPAH and HPAH has been challenging, the search for modifying exposures and genes has proven even more elusive. Analyses of a number of genes chosen for their potential to affect vascular function have been performed with variable success. For example, candidate gene approaches that select those genes or pathways that have a role in vascular structure and function and that have known variants that confer differences in function have been used most commonly. The list of explored candidate modifier loci is long, and includes serotonin transporter (5-HTT) and receptors, nitric oxide (NO) synthases, TGFβ1, endothelin and endothelin (ETA) receptors, vasoactive intestinal polypeptide, urea cycle enzymes (including carbamyl phosphate synthetase 1), ETA receptors, ion channels, monoamine oxidases, and sex hormone pathway members.

Given the challenge of correctly hypothesizing a biologically relevant candidate or candidates, discovery-based methods to determine contributing common variants such as the use of genome-wide association studies are an appealing approach. Rodriguez-Murillo et al. employed this approach to study HPAH in 15 families that segregated *BMPR2* mutations. They combined dense single-nucleotide polymorphism array data with novel biostatistical analyses to perform a multiscan linkage procedure aimed at improving power and precision for localization of linked loci. Their findings suggest several additional loci that may contain modifiers of disease penetrance among *BMPR2* mutation carriers, the strongest of which was a region on 3q22 (median log

of the odds score of 3.43). While a lack of power due to relatively small sample size made it impossible to identify precisely the associated gene or genes in this region, this locus is now a region of intense interest (57).

While IPAH and HPAH are diseases specifically of the pulmonary vasculature, few studies to date have explored the genetic variations specific to the lungs themselves. Recently, Aldred et al. advanced the hypothesis that the acquisition of somatic mutations within the lung participates in disease pathogenesis among patients with IPAH and HPAH with and without *BMPR2* mutations (34). Using a genome-wide copy number microarray approach, confirmed by fluorescent in situ hybridization as appropriate, they found evidence of several somatic alterations throughout the lung vasculature of patients with end-stage IPAH and HPAH. Specifically, they detected acquired chromosomal abnormalities (including chromosome 13 loss as well as female-specific X chromosome inactivation) in a small number of patients with PAH. These changes were fairly specific to the endothelial cells, and present throughout the lungs including plexiform lesions (34). This work is provocative as the first study to document somatic mutations in the endothelial cells of end-stage PAH lungs, and suggests additional loci of interest. Furthermore, the finding of differential changes between endothelial and smooth muscle cells would be consistent with the perceived central role of endothelial cells in the pathogenesis of disease (58). Additional studies are needed to determine that somatic mutations are causative in PAH, including evidence that such mutations occur before any detectable disease (29).

## 48.7 MOLECULAR AND CELLULAR PATHOGENESIS

Regardless of cause, PAH is a devastating pulmonary vascular disease that results in a progressive increase in pulmonary vascular resistance. This ultimately leads to right ventricular failure and death (59). While persistent vasoconstriction is certainly a component of disease pathogenesis, the predominant histopathologic finding in PAH is a profound remodeling of the smallest pulmonary arteries, characterized by intimal hyperplasia, medial hypertrophy, proliferation and fibrotic changes of the adventitial layer as well as infiltration by circulating cells (60). The molecular and cellular processes involved remain unclear. The prevailing hypothesis involves proliferation and dysfunction of both endothelial and smooth muscle cells, as well as fibroblast activation and the recruitment of circulating cells (58). Intense cellular proliferation, as well as prior evidence of endothelial cell monoclonality and somatic endothelial cell gene mutations, highlights the features that suggest PAH may be a variant of an angioproliferative disorder with neoplastic features as noted above (30–34). Naturally, molecular and cellular pathogenesis is an area of investigation

in the field, with a considerable interest in the role of *BMPR2*, but not limited to this or other TGF $\beta$  receptors and their signaling pathways.

### 48.7.1 *BMPR2*-Mediated Pathogenesis

The TGF $\beta$  superfamily is composed of receptors and their small ligands that, in concert, regulate many sequences of cell and tissue growth, wound healing and inflammatory responses; they are even involved in neoplastic transformation of cells (61). This “superfamily” is made up of serine–threonine cell surface receptors that signal through intracellular pathways by phosphorylating Smad proteins, which translocate to the nucleus to regulate gene expression via various transcription factors. The receptors’ stimulants to signal are ligand cytokines (most typically various TGFs or BMPs). Evidence is growing that imbalanced activation of TGF $\beta$  receptor superfamily signaling contributes to the pathogenesis of PAH, and complicates our understanding of the origins of disease. Specifically, enhanced activation of the traditional TGF $\beta$  receptors, coupled with reduced activity of mutated *BMPR2*, may promote the pathogenetic events that cause PAH (62).

While many hypotheses exist to explain the contribution of *BMPR2* to pathogenesis, the prevailing view centers on TGF $\beta$  “imbalance.” That is, TGF $\beta$  family signaling promotes proliferation of endothelial and smooth muscle cells in the smallest pulmonary arteries without sufficient counter regulatory control by *BMPR2*. Signaling through *BMPR2* is unable to serve as a molecular “brake” on exuberant cell proliferation (63,64). Consistent with this hypothesis, *BMPR2* is reduced in the lungs of patients with mutations, as well as patients with other forms of PAH including but not limited to IPAH (63).

*BMPR2* has been shown to influence intracellular signaling via at least two groups of molecules, Smads and mitogen-activated protein kinases (MAPKs) (Figure 48-4) (55). *BMPR2* mutations alter Smad signaling in a mutation-specific manner but predictably result in potentiation of p38 MAPK signaling and cell proliferation in vitro (58,65).

**48.7.1.1 Smad-Dependent BMP Signaling.** In the presence of ligand, activated receptors phosphorylate cytoplasmic signaling proteins known as Smads, which are responsible for TGF $\beta$  superfamily canonical signaling transduction. BMPs signal via a specific set of receptor-mediated Smads (R-Smads), Smad 1, 5, and 8, which form a complex with the common partner Smad (Co-Smad), Smad-4, and translocate to the nucleus (4). Target gene transcription is regulated by a variety of mechanisms, including direct binding of the Smad complex to DNA, interaction with other DNA proteins, such as AP-1 and TFE-3, and recruitment of transcriptional coactivators or corepressors (66).

**48.7.1.2 MAPK-Dependent BMP Signaling.** Although Smad signaling is recognized as the canonical BMP

FIGURE 48-4 Schematic diagram of BMP signaling.

signaling pathway, there is an evidence that MAPKs, including  $p38^{\text{MAPK}}$  (MAPK14; OMIM 600289),  $p42^{\text{MAPK}}$  (MAPK1 or ERK2; OMIM 176948),  $p44^{\text{MAPK}}$  (MAPK3 or ERK1; OMIM 601795), and JNK/SAPK are modulated by BMPs and TGFβs in certain cell types (65). Disruption of Smad-dependent signaling may not be the most important pathway downstream of BMPR2 in the pathogenesis of PPH. The specific pathway activated by BMPR2 may depend on whether preformed type I/type II heterodimers are stimulated by ligand (Smad-dependent pathway), or whether ligand leads to recruitment of type I and II receptors to the signaling complex (MAPK-dependent pathway). It appears that preformed complexes are heterodimers containing one type I and one type II receptor, but ligand-recruited complexes consist of homo-oligomerized type I receptors and one type II receptor. Structural differences in the receptor complex may account for the selection of distinct signaling pathways.

**48.7.1.3 ACVRL1 and Endoglin.** Mutations in the TGFβ type I receptor, *ACVRL1* (OMIM 601284), *ENG* (OMIM 131195) (a TGFβ receptor accessory protein), and *SMAD4* associate with HHT. HHT is a condition frequently complicated by complex vascular lesions as well as variable expressivity; in some situations, PAH clinically identical to IPAH and HPAH will occur (67,68). The presence of a similar phenotype to IPAH and HPAH in HHT highlights the notion that the effects of TGFβ on vascular cell differentiation and proliferation are complex, and are likely influenced by additional genetic and environmental factors.

**48.7.1.4 Serotonin.** Serotonin (5-hydroxytryptamine; 5-HT) is implicated in the pathogenesis of PAH although human genetic and functional studies have shown mixed results. Pulmonary artery smooth muscle cells (PASMCs)

from patients with PAH display a greater proliferative response to 5-HT when compared to PASMCs derived from normal controls (69). Patients with PAH have a sustained increase in circulating plasma levels of 5-HT (70). Ingestion of anorexigens of the fenfluramine group is reported to increase the risk of developing PAH, and these drugs are known to inhibit 5-HT uptake by transporters and to augment circulating 5-HT levels. Lung tissue taken from PAH patients displays increased expression of 5-HTT (69). Homozygosity for a 5-HTT (SLC6A4; OMIM 182138) promoter polymorphism (L-allele) is found to be significantly increased in a PAH patient population as compared to a control population (65% vs 27%); this polymorphism is associated with increased gene transcription and 5-HT-induced PASMC proliferation (69). However, efforts to validate the L-allele polymorphism's association with PAH have yielded mixed results due to either small effect or insufficient sample size, or both (71,72).

**48.7.1.5 Transforming Growth Factor β1.** Given the interest in a potential signaling imbalance between canonical TGFβ signaling and BMP signaling, enhanced TGFβ signaling has been postulated to promote PAH among susceptible subjects. For example, among *BMPR2* mutation carriers, there may be common variants that promote disease expression such as penetrance or younger age at diagnosis. While not yet independently replicated, among our cohort of HPAH families, TGFβ1 common polymorphisms appear to modify disease expression. Specifically, *BMPR2* mutation carriers with TGFβ1 common variants that enhance TGFβ signaling had a younger mean age at diagnosis (about 7–10 years) of HPAH compared to those patients with variants associated with reduced TGFβ activity. Furthermore, those with the “less-active” TGFβ1 common variants had later age at diagnosis, and

lung Smad2 protein expression (a downstream marker of TGF $\beta$  activity) was higher among HPAH patients compared to controls (73).

**48.7.1.6 Other Contributors to Pathogenesis.** PSMCs derived from PAH patients have low messenger RNA (mRNA) levels for a voltage-gated potassium channel ( $K_{\text{vee}}$  channel) and decreased channel current, together with a corresponding increase in intracellular calcium levels as compared to controls (74,75). Intracellular calcium is a widely recognized stimulant for PSMC contraction and hypertrophy. The  $K_{\text{vee}}$  channel hypothesis is strengthened by the finding that some anorexigens block these channels in PSMCs.

Patients with PAH produce increased levels of thromboxane and endothelin-1, both vasoconstrictors, and decreased levels of both prostacyclin and NO synthase, which would inhibit formation of these vasodilators (76,77). It is possible that an imbalance between vasodilators and vasoconstrictors contributes to the pathogenesis of PAH.

Several studies have identified a possible role for angiopoietins (ANGPT1; OMIM 601667) in PAH, but whether these growth factors cause or prevent the disease remains unclear (78–80). One study demonstrated that administration of angiopoietin-1 (Ang-1) had protective effects in the rat model of monocrotaline-induced pulmonary hypertension, and hypothesized that this was due to the rescue of endothelial cells from apoptosis (80). Another study reported elevated levels of Ang-1 in lung tissue from PPH patients and demonstrated an associated decrease in BMPR-1A levels (79). The authors suggested that Ang-1 promotes smooth muscle cell hyperplasia through down-regulation of BMP signaling pathways. Subsequent work suggested overexpression of Ang-1 in rats caused pulmonary hypertension, while alternative studies have shown Ang-1 signaling is protective (81,82). While not indicative of causation, plasma levels of the angiogenic factors Ang-1, angiopoietin-2 (Ang-2), vascular endothelial growth factor, and soluble Tie2 were recently demonstrated to be elevated in IPAH patients. Of those factors, only Ang-2 improved with therapy and associated with improvement in hemodynamics. Ang-2 mRNA and protein were elevated in the plexiform lesions of IPAH patients, as well (83).

## 48.8 DIAGNOSIS

A normal resting mean pulmonary artery pressure is 8–20 mmHg. The diagnosis of any type of pulmonary hypertension requires the presence of a resting mean pulmonary artery pressure of  $\geq 25$  mmHg measured by cardiac catheterization. IPAH and HPAH are established clinically by confirming the presence of precapillary pulmonary hypertension (PAH), which is defined as pulmonary hypertension (mean pulmonary artery pressure  $> 25$  mmHg at rest) with a pulmonary capillary wedge pressure measurement  $\leq 15$  mmHg on cardiac

catheterization, in conjunction with the exclusion of other secondary causes of pulmonary hypertension (84). Secondary causes of PAH are more common and should be carefully excluded before the diagnosis of IPAH or HPAH is established. Some secondary causes of PAH include lung disease, heart disease, pulmonary embolism, and various other conditions including rheumatologic disease, cirrhosis, and HIV infection (see Table 48-1).

PAH may be suspected in individuals with the following symptoms when other known causes are absent. Initial symptoms include dyspnea (60%), fatigue (19%), chest pain (7%), palpitation (5%), syncope (8%), and edema (3%) (9). The clinical diagnosis of PAH was often delayed in the past, perhaps in part related to the fact that the typical symptoms are nonspecific, and also that the index of suspicion by general physicians was relatively low. General awareness has improved and widespread availability of echocardiography has greatly facilitated timely diagnosis.

Physical examination may reveal right ventricular heave, accentuation of the pulmonic component of the second heart sound, or cardiac murmur, such as tricuspid regurgitation occurring as a result of right ventricular dilation (9). Later in the course of disease, signs of right ventricular failure such as increased venous pressure, edema, or hepatomegaly occur in most patients. Electrocardiography (ECG) may reveal changes suggestive of right atrial or right ventricular hypertrophy. In individuals with pulmonary hypertension associated with cardiac causes, ECG may also reveal additional changes (left atrial hypertrophy) that suggest causes other than PPH. Pulmonary function testing may show mild restriction or may be normal in patients with PAH, but in patients with parenchymal lung diseases will usually reveal evidence of either obstructive or restrictive disorders or both (38).

In patients with IPAH and HPAH, chest radiography may show enlargement of pulmonary arteries and cardiomegaly from right ventricular or atrial enlargement, but the lung parenchyma appears normal. In individuals with pulmonary hypertension associated with parenchymal lung disease, chest radiography may reveal changes typical of interstitial or obstructive lung disease. Perfusion lung scanning is normal or mottled, or alternatively may reveal segmental or larger perfusion defects suggestive of pulmonary embolism. Chest computed tomography (CT) scanning shows normal lung parenchyma in individuals with IPAH and HPAH, while high-resolution imaging may show changes of interstitial lung diseases or emphysema in pulmonary hypertension associated with parenchymal lung disease. CT angiography has improved greatly and is noninvasive, so it may be helpful in the evaluation for suspected intravascular thrombi in the central pulmonary vasculature in some patients.

While not the definitive diagnostic study, echocardiography can provide an estimate of systolic pulmonary artery pressure and reveal changes of the right ventricle due to pulmonary hypertension (85). Echocardiography

is also valuable to screen for valvular or left ventricular diseases as alternative causes of pulmonary hypertension. Clinical confirmation of the diagnosis of PAH requires cardiac catheterization to measure pulmonary artery pressure and to exclude other cardiac abnormalities (84). When noninvasive testing suggests PAH, the catheterization should be performed in a laboratory that is experienced and prepared to perform an acute pulmonary vasodilator trial, which is often done using inhaled NO. Alternatively, provocative testing for other cardiac defects should be routinely employed when appropriate, such as observing the hemodynamic response of filling pressures to fluid challenge when there is clinical suspicion of left ventricular diastolic dysfunction.

Cardiac catheterization is necessary for confirmation of the disease in patients with suspected pulmonary hypertension (38,84), but in the current era, it rarely reveals unsuspected new findings. Recent advances of noninvasive thoracic and cardiac imaging often provide a specific diagnosis as the cause of pulmonary hypertension even before confirmation by cardiac catheterization. Many conditions that are associated with pulmonary hypertension, such as pulmonary embolism or parenchymal lung disease, are accurately and safely diagnosed by noninvasive imaging in the current era. Modern thoracic and vascular imaging by CT or magnetic resonance imaging provide high-resolution images that are comparable to invasive angiography.

Lung biopsy is not indicated to confirm a clinical diagnosis of PAH, but when histopathology is available in individuals with IPAH and HPAH (e.g. a lung explanted at the time of transplant), it usually confirms occlusion of small pulmonary arteries and in many cases, plexiform lesions with other lung structure being normal. Several pathophysiologic features contribute to small pulmonary artery occlusion, including proliferation of the intima and media of the vessel wall, vasospasm, and microthrombosis (7). Because surgical lung biopsy requires general anesthesia, the accompanying risk is rarely appropriate in patients in whom the clinical testing indicates IPAH or HPAH, but rarely lung biopsy does reveal other conditions (86). Extremely rarely, some patients demonstrate the typical clinical features of IPAH or HPAH but have a rapidly fatal course, and postmortem studies discover microembolic tumor occluding pulmonary microvessels.

Improvements in diagnosis are needed and will depend on the development of a method to identify and validate biomarkers that reflect the underlying vascular disease process itself, rather than the pulmonary hypertension per se, which is not the root problem itself, but is instead the consequence of the underlying pulmonary vascular disease. Pulmonary hypertension does not even begin until the pulmonary vascular disease is already in advanced stages, so any increase in pulmonary artery pressure reflects an advanced degree of vascular damage. Changes in right ventricular function and anatomy are even further distant in the sequence of events. Improved

molecular and cellular understanding about the central pathogenesis of PAH should lead to the development of early biomarkers of the vascular disease itself.

## 48.9 MANAGEMENT

Optimal therapy for PAH continues to improve, and many new and promising agents are still in investigational phases, so all patients should be offered consultation in specialized centers to access the best current treatment. Specialty centers for diagnosis and therapy of PPH are available all across the United States (see the Pulmonary Hypertension Association website at <http://www.phassociation.org>). New medications for PAH are costly and their availability differs by country, in part due to approval by regulatory agencies, so optimal therapy may differ geographically around the world (87). Most patients seek medical care only after symptoms develop, which occurs late in the course after extensive numbers of small pulmonary arteries have been lost. For the future, as further knowledge develops about the earliest pathogenesis of PAH, biomarkers of the vascular disease itself will be identified to diagnose the disease before extensive vascular loss, at a phase during which prevention of progression should have a greater possibility of success.

### 48.9.1 Approved Therapies in the United States

Despite considerable advances in the genetic, molecular, and cellular understanding of PAH, disease-specific medicinal options remain limited for patients but are discussed briefly below.

**48.9.1.1 Adjunctive Therapies.** Diagnosis of PAH does not necessarily preclude an active lifestyle. Patients should engage in activities appropriate to their functional status in order to prevent deconditioning. Regular exercise also provides a benchmark for patients to ascertain any change in their condition. Appropriate caution concerning physical activity is advised for patients with advanced pulmonary hypertension with symptoms of dizziness, chest pain, or severe dyspnea because there is increased risk for life-threatening syncope. In general, patients are cautioned to maintain physical activity at a level that is tolerated but not stressful to them physically or mentally. The role for cardiopulmonary rehabilitation and maintenance is an area of active investigation, with evidence that it is safe and efficacious in a monitored setting (88).

Chronic anticoagulation therapy, diuretics, and supplemental oxygen are used routinely in the care of individuals with pulmonary hypertension, but have not been rigorously studied (87). The rationale for anticoagulant therapy is based on the presence of risk factors for venous thromboembolism, such as heart failure and a sedentary lifestyle. Warfarin has been evaluated in only

two small uncontrolled studies, but is routinely recommended with a target International Normalized Ratio between 1.5 and 2.5.

Chronic hypoxemia occurs in advanced stages of disease and is often the result of impaired cardiac output, which results in desaturation of mixed venous blood. It may also be caused by right-to-left shunting through a patent foramen ovale. When chronic hypoxemia develops, oxygen administration is indicated to maintain arterial oxygen saturation at a level above 93%.

Substantial clinical improvement in functional status as well as in fluid balance can be achieved by diuresis alone in many patients with right heart failure (87). The value of cardiac glycosides in treating isolated right heart dysfunction is controversial. Because neurohormonal sympathetic activation has been demonstrated in pulmonary hypertension, some authors propose treatment with digoxin for its sympatholytic properties, but no data are available from prospective, randomized, placebo-controlled trials to provide clear guidelines.

Pregnancy and labor increase the demand on the cardiorespiratory system, so they are generally contraindicated in patients with pulmonary hypertension, and contraception is generally recommended for women of childbearing age who have PAH. However, recent interest in the potential role of sex hormones in the pathogenesis of PAH, as well as concerns about sex hormone exposures in cardiovascular disease in general, some clinicians recommend alternative forms of birth control to medical hormone therapy. Finally, for all patients vaccination, including annual influenza vaccination, is encouraged unless contraindicated.

**48.9.1.2 Calcium Channel Blockers.** Because these oral agents are widely used for other disorders, they are familiar to most physicians. It is widely accepted that a small minority (~10%) of PAH patients respond favorably to calcium channel blockers (CCBs), sometimes for many years or indefinitely, but randomized controlled trials have not been performed (87). As noted above, all patients should undergo acute vasodilator testing with a short-acting vasodilator (inhaled NO, adenosine, epoprostenol) during diagnostic heart catheterization (84). Patients who may benefit from long-term therapy with CCBs can be identified by a favorable response to an acute vasodilator challenge. The safest approach is with the use of short-acting agents, such as intravenous prostacyclin, adenosine, or inhaled NO, during right heart catheterization. In a retrospective analysis of 557 consecutive patients with PAH, Humbert et al. found that fewer than 7% had a sustained benefit from therapy with a calcium channel blocker (87). During acute vasodilator challenge, most patients who had a long-term response to CCBs had a marked improvement in their pulmonary hemodynamics (i.e. mean pulmonary artery pressure decreased by >10 mmHg, to a value >40 mmHg, with a normal or high cardiac output). The occurrence of severe, life-threatening hemodynamic compromise

during an acute vasodilator challenge with CCBs is well documented, and these agents should not be used as initial agents for acute pulmonary vasodilator testing.

**48.9.1.3 Prostaglandin Analogs.** Prostacyclin is a prostaglandin produced by both vascular smooth muscle and endothelium that stimulates vasodilation, inhibits smooth muscle growth (antiproliferative effects), and inhibits platelet aggregation. Prostaglandins target the prostaglandin I receptor, which is found in blood vessels, leukocytes, and thrombocytes. This receptor is coupled with Gs proteins and when stimulated, activates adenylate cyclase, leading to an increase in intracellular cyclic adenosine monophosphate (89).

Epoprostenol (FLOLAN) is a prostacyclin analog that is administered by continuous intravenous infusion because its half-life is only 3 min in the circulation. For chronic home administration, epoprostenol is infused by a portable infusion pump connected to a permanent tunneled catheter in the subclavian vein. Approval of epoprostenol in the United States followed a randomized controlled trial in 81 patients with PAH in NYHA functional class III or IV (90). Participants were randomly assigned to receive either conventional therapy alone (including warfarin, diuretics, oxygen, and oral vasodilators) or conventional therapy plus continuous intravenous epoprostenol. After 12 weeks, patients in the epoprostenol group had functional improvement as demonstrated by improved 6-min walk-test results. In the epoprostenol group, the mean pulmonary artery pressure decreased 8% in the epoprostenol group, while it increased 3% in the control group. Mean pulmonary vascular resistance decreased 21% in the epoprostenol group and increased 9% in controls. Eight patients in the conventional therapy group died during the study, whereas no deaths occurred in the epoprostenol group.

Common epoprostenol side effects include jaw pain, nausea, headache, flushing, and diarrhea. Complications from the delivery system include exit-site infections and bleeding, bacteremia/sepsis, catheter fracture, delivery malfunction that may result in sudden severe decompensation, and paradoxical embolization. In the past, patients began continuous intravenous epoprostenol with the understanding that they would continue it lifelong or until lung transplantation. As other effective therapies have become available in the past few years, data are emerging to suggest that selected patients may successfully transition off parenteral therapy to alternative prostanoids or other PAH-specific therapies.

Complications related to the central venous catheter required for intravenous infusion of prostacyclin led to the development of treprostinil, a stable prostacyclin analog approved in the United States to be administered by continuous intravenous or subcutaneous infusion (91,92). It otherwise displays the same pharmacologic and hemodynamic effects as seen with epoprostenol. Treprostinil has been an approved therapy for PAH in the United States since 2002 and some patients with

PAH in whom life-threatening complications developed with intravenous epoprostenol have been safely switched to subcutaneous treprostinil (93). Inhaled treprostinil appears efficacious although placebo-controlled trials using this agent are limited (94). The inhaled delivery system facilitates deposition in alveoli, thereby improving selective effect on pulmonary versus systemic vessels, preferentially on those pulmonary vessels located in well-ventilated regions. The relatively short duration of action requires dosing six or more times daily, which may hinder adherence to therapy.

**48.9.1.4 ET Receptor Antagonists.** There are two ET receptor antagonists currently approved for use in the United States: bosentan and ambrisentan. While similar, these drugs have different affinities for endothelin type A (ET<sub>A</sub>) and endothelin type B (ET<sub>B</sub>) receptor antagonism, which may theoretically lead to differing pharmacologic and therapeutic effects.

Bosentan (Tracleer) is an orally active dual ET receptor (ENDRA and ENDRB; OMIM 131243 and 131244) antagonist. Endothelin-1 has many different biological actions, including vasoconstriction and stimulation of proliferation of vascular smooth muscle cells. The effects of endothelin-1 are mediated through the ET<sub>A</sub> and ET<sub>B</sub> ET receptors. Activation of ET<sub>A</sub> receptors causes vasoconstriction and proliferation of vascular smooth muscle cells, whereas ET<sub>B</sub> receptors mediate pulmonary endothelin clearance and induce the production of NO and prostacyclin by endothelial cells. Two randomized, double-blind, placebo-controlled trials have evaluated the efficacy of oral bosentan in patients with PAH. In a study of 33 patients in NYHA in functional class III (95) who were randomly assigned to receive placebo or bosentan, patients receiving bosentan had an increase of 76 m in the 6-min walk test, as well as significant improvements in pulmonary artery pressure, cardiac output, and pulmonary vascular resistance. In a subsequent study (96), 213 patients in NYHA functional class III or IV were randomly assigned to receive placebo or bosentan; the treatment was associated with increase in the 6-min walk of 52 m in patients with PAH. Patients receiving bosentan also had improvement in the time to clinical worsening. Although there is some preliminary evidence of sustained efficacy with 12 months of therapy, the long-term effects of bosentan require further evaluation. Bosentan is metabolized by the liver and may induce an increase in hepatic aminotransferase levels. Development of abnormal hepatic function appeared to be dose dependent, in support of the approved dose of 125 mg twice daily. Elevations in aminotransferase levels to more than eight times the upper limit of normal occurred in 3% of patients receiving 125 mg twice daily and 7% of patients receiving 250 mg twice daily. Monthly monitoring of liver function tests is necessary, but there are no reports of permanent liver dysfunction or failure with bosentan, even though thousands have received the drug.

Ambrisentan is an oral selective ET<sub>A</sub> receptor antagonist, approved in the United States since 2007. This specific antagonism presumably blocks the vasoconstrictor effects of ET receptors while maintaining the vasodilator and clearance effects of ET<sub>B</sub> receptors. It was shown to improve exercise capacity and delay clinical worsening in patients with PAH in two concurrently run, 12-week multicenter randomized controlled trials (i.e. Ambrisentan in PAH, Randomized, Double-Blind, Placebo-Controlled, Multicenter, Efficacy Studies 1 and 2 (ARIES-1 and ARIES-2)) (97). This drug may provide sustained improvements in pulmonary hemodynamics in patients with PAH who receive long-term treatment and these changes correlate with improvements in exercise capacity, but further studies are needed (98). Cases of acute hepatitis have been described in patients taking selective ET<sub>A</sub> blockers, including one fatality, which emphasizes the importance of serial monitoring of liver function.

**48.9.1.5 Phosphodiesterase-5 Inhibitors.** Phosphodiesterase type 5 (PDE-5) inhibitors, such as sildenafil (Viagra), have an acute pulmonary vasodilator effect. NO, released by vascular endothelial cells, causes vasodilation of the lung vessels by increasing production of cyclic guanosine monophosphate (cGMP) via activation of soluble guanylyl cyclase, ultimately leading to smooth muscle cell relaxation (99). In the lung, cGMP is hydrolyzed rapidly by PDE-5 to inactive compounds. Inhibition of cGMP results in vasodilation (100). Two PDE-5 inhibitors, both oral delivery, are approved for PAH therapy in the United States: sildenafil and tadalafil. For each, the most common side effects are headache, flushing, back pain, dyspepsia, and insomnia. Patients may experience transient mismatching of ventilation and perfusion upon initiation, so caution should be taken in particular when starting these or any other PAH-specific medications.

## 48.9.2 Surgical Therapy: Lung Transplantation

Lung transplantation is an effective treatment for some individuals with PAH (26,27). Transplantation of both lungs is currently recommended although single-lung and heart-lung (heart and both lungs en bloc) transplantation has been used successfully. Typical upper age limits for recipients are 50 years for heart-lung transplantation, 60 years for bilateral lung transplantation, and 65 years for single-lung transplantation. Insufficient availability of donor lungs is a major limitation, but even for those fortunate enough to be recipients, long-term survival is limited by chronic rejection for most, so that the mean survival after lung transplantation is only 4 years. Although some patients have done very well for long periods, even sometimes for decades after lung transplantation, they represent only a small minority of all the recipients.

Ironically, the availability of effective medical therapy has complicated the decision about timing for transplantation. Before the availability of effective medical therapies, functional status correlated closely with survival in individual patients, so that lung transplantation was appropriate for patients with severely limited functional capacity (i.e. NYHA class III or IV). In the current era of effective medical therapy, it is much more difficult to estimate survival for individual PAH patients, and it is thereby problematic to decide when the high risk of lung transplantation is warranted. Medical therapy may appear effective in many patients who have good functional status, but their ability to survive even a modest intercurrent illness may be severely compromised by limited cardiorespiratory reserve.

## 48.10 COUNSELING

### 48.10.1 Clinical Screening and Surveillance for PAH

Clinical surveillance of asymptomatic family members at risk has been recommended since the 1998 World Health Organization Symposium on PAH. Most recently, guidelines from the 2008 meeting suggested echocardiographic screening of family members who are at risk, at intervals of 3–5 years, to enable early detection and treatment (17). There are no reports of the frequency of compliance with this recommendation, and its performance is influenced by the fact that many health insurers do not provide coverage for screening tests for individuals unless symptoms or signs are present. At Vanderbilt, we have on several occasions detected pulmonary hypertension in asymptomatic carriers of *BMPR2* gene mutations, the most recent of whom was an adolescent male who subsequently had PAH confirmed by cardiac catheterization.

### 48.10.2 Agents and Circumstances for At-Risk Subjects to Avoid

Appetite suppressant medications, such as fenfluramine/phentermine, dexfenfluramine, and amfepramone (diethylpropion), have all been associated with PAH (2,48). Amphetamines, cocaine, and related compounds causing vasoconstriction have anecdotal association with PAH and could be risk factors (22). Methamphetamine has recently been associated with cases of PAH, of great concern given the surge in the use of this drug of abuse (101).

Other medications that have anecdotal suggestion of risk include estrogen compounds used as oral contraceptive or replacement therapy (22). Anecdotal reports of association of pregnancy with onset of PAH give concern about the possible risk of pregnancy as a trigger; however, there is no consensus about the safest effective birth control in women who have PAH or who are at risk for it in PAH families. The physiologic stress of pregnancy in an affected individual is significant, and maternal

mortality is believed to be substantial, but newer effective therapies may decrease this risk (102).

Hypoxia that accompanies high altitude is associated with pulmonary vasoconstriction and PAH in susceptible individuals. Therefore, individuals with PAH should avoid hypoxia.

### 48.10.3 Genetic Counseling

PAH in families is inherited in an autosomal dominant manner. However, the average penetrance of *BMPR2* mutations is ~20%, and this reduced penetrance makes predictions of who will develop PAH in their lifetime unreliable. If a parent of a proband has a *BMPR2* mutation, the risk to the sibs of inheriting the gene mutation is ~50%; however, because of reduced penetrance, the risk to a sib of developing HPAH is ~10% (50% risk of inheriting the disease allele  $\times$  20% risk of penetrance). Similarly, the children of an individual with a *BMPR2* mutation are at 50% risk of inheriting the mutant allele; however, because of reduced penetrance, the risk to offspring of developing HPAH is ~10% (50% risk of inheriting the disease allele  $\times$  20% risk of penetrance). Prenatal testing is available through laboratories offering such testing although decisions on the use of prenatal testing should depend on the family at risk. There is no consensus on the appropriateness of prenatal testing at this time.

### 48.10.4 Mutation Testing of Relatives at Risk

Direct molecular genetic testing of *BMPR2* alleles for mutations is available in at least four clinical laboratories in the United States. Genetic testing for *BMPR2* gene mutations should occur within the framework of a comprehensive approach to provide not only medical care as needed but also genetic counseling irrespective of the result of mutation testing. The Genetic Information Non-discrimination Act of 2008 (103) guarantees the protection of subjects tested for genetic variants although the ramifications of testing may extend far beyond that of health insurance and employment, and thus appropriate counseling is critical.

The use of *BMPR2* molecular genetic testing to clarify the genetic status of at-risk relatives may be helpful, especially in families in whom a specific mutation is known. A negative test result in which the subject does not have a mutation can be very helpful because it indicates that the subject and his/her progeny possess the same risk as the general population; thus, they can safely forego clinical screening. As noted above, because of reduced penetrance, the approximate pretest probability for the first-degree relative of an affected member of an HPAH family is ~10% (50% risk of inheriting the disease allele  $\times$  20% risk of penetrance =  $0.50 \times 0.20 = 0.10$ ) of developing HPAH during the subject's lifetime. If there is

a known mutation in the family for which there is a reliable test, then if the first-degree relative tests negative for the mutation, his or her risk for developing HPAH falls from ~10% to that of the population (~1–15 per million subjects), so it changes 100,000-fold. Conversely, if he or she tests positive for the mutation, the risk changes from ~10% to ~20%, or a twofold change. Thus a positive-test result changes the pretest probability only slightly, whereas a negative-test result changes risk dramatically.

Detection of a responsible germline mutation in a sporadic PAH patient (those typically considered to have IPAH) may have the greatest overall impact, because it converts the concept of the disease from sporadic to familial, thereby revealing the possibility of a heritable disease for which one's bloodline kin are now at increased risk. If the patient has siblings or children, they may be surprised and alarmed by the new knowledge and the unanticipated personal risk. Of course, the risk already existed before testing, and was simply unrecognized, but the emotional impact of revealing the true risk has many possible complications—this highlights the critical role of extensive pretest counseling.

## ACKNOWLEDGMENTS

We thank the patients and family members throughout the world whose participation in the studies described here made the substantial progress possible. In addition, we thank Lisa Wheeler for her dedication as a tireless family advocate and coordinator of our pulmonary hypertension program for over 15 years, as well as her assistance in preparation of this manuscript. This work was supported by NIH NHLBI PO1 HL 072058, NIH NHLBI K23 HL098743, and General Clinical Research Center RR 00095.

## ABBREVIATIONS

PAH – pulmonary arterial hypertension

HPAH – heritable pulmonary arterial hypertension

IPAH – idiopathic pulmonary arterial hypertension

## Biographies

**Dr Eric D Austin, MD, MSCI**, is a pediatric pulmonologist and physician–scientist with a combined laboratory-based and patient-oriented translational research program that focuses on pulmonary hypertension and other cardiopulmonary morbidities in children and adults with and without pre-existing known genetic risks. Following pediatric training at the University of Colorado, he performed subspecialty training in pulmonary medicine at Vanderbilt University. Dr Austin joined the faculty at Vanderbilt in 2008, and remains an Assistant Professor of Pediatrics in the Division of Allergy, Immunology, and Pulmonary Medicine. In addition to the care of children with simple and complex pulmonary diseases, his specialty training was also in translational research techniques, including the design and maintenance of longitudinal cohorts of patients and family members with cardiopulmonary disease or genetic risk of disease. His research work focuses on evaluating the manner in which genetic, biochemical, environmental and other abnormalities promote phenotypic expression of pulmonary hypertension and other cardiopulmonary diseases.

**John A Phillips III, MD, PhD**, is the David T. Karzon Professor of Pediatrics at Vanderbilt University School of Medicine. He is also the Director, Division of Medical Genetics and Genomic Medicine, Professor of Pathology, Microbiology, Immunology and Medicine. Dr Phillips' has successfully cared for children and adults with genetic disorders for many years while maintaining a thriving research program as well. His research interests are in determining the molecular basis, pathogenesis, and treatment of Mendelian disorders. Current studies include the following: 1) genetic defects in the growth hormone (GH) synthetic pathway and regulation of alternative splicing of GH1 transcripts; 2) genetic basis of pulmonary arterial hypertension (PAH)—this work includes his discovery along with Drs. Loyd, Newman and colleagues of BMPR2 gene defects in familial pulmonary arterial hypertension; 3) genetic basis of autonomic disorders; 4) genetic basis of idiopathic pulmonary fibrosis (IPF) and, 5) determining the therapeutic effects of BH4 on blood Phenylalanine reduction, development and global function of subjects with Phenylketonuria (PKU).

**John H Newman, MD**, is Professor of Medicine and the Elsa S Hanigan Chair in Pulmonary Medicine at Vanderbilt University School of Medicine. For nearly 30 years, Dr Newman has successfully studied the complex nature of the pulmonary circulation, including the genetic basis of pulmonary hypertension—an interest that started in 1980 when he and Dr Loyd encountered their first cases of familial pulmonary hypertension. Mentor, physician-scientist, and clinician, Dr Newman has authored over a hundred articles in scientific publications and numerous books, book chapters, and review papers. Dr Newman continues to investigate a wide variety of questions to examine such issues as gene-to-gene interactions in pulmonary hypertension, the role of phosphodiesterase type 5 (PDE5) as a modulator in right ventricular (RV) failure, and gender and endothelin determinants of RV function in pulmonary hypertension.

**James E Loyd, MD**, Rudy W Jacobson Professor of Medicine Dr Loyd is a physician-scientist with a successful record of translational research and clinical care of patients with complex cardiopulmonary diseases. His primary areas of research focus have been pulmonary vascular disease, pulmonary fibrosis, and fibrosing mediastinitis. For example, Dr Loyd, along with Dr Newman and colleagues, has investigated pulmonary hypertension continuously since 1980. Their work with Dr Phillips and other investigators using a cohort of families with pulmonary hypertension resulted in their identification of BMPR2 as the primary gene associated with familial pulmonary arterial hypertension in 2000. Dr Loyd continues to explore genetic and other modifiers of pulmonary arterial hypertension, using translational research approaches incorporating cellular and animal models as well as human studies of disease expression.

### 49.1 INTRODUCTION

#### 49.1.1 Historic Perspective

The evolution of our recognition and understanding of hereditary hemorrhagic telangiectasia (HHT; OMIM 187300) begins with the descriptive science of the nineteenth century and continues through the current era of molecular medicine. Only in the past two decades have modern genetic approaches made clear that the previous view of HHT as a single entity was overly simplistic, and that a more accurate concept is of a family of closely related conditions that share similar, but not identical, molecular bases and clinical courses.

The history of HHT might be said to start in 1864, when Sutton described a family with apparent autosomal dominant epistaxis, including at least two affected individuals with a history of hemoptysis, one of whom died at the age of 60 of what was said to be “ruptured blood vessel of the lungs” (1). Even with no mention of such other symptoms and signs as telangiectasias, this likely represents what we now regard as HHT.

Although the following 30 years included a number of reports of families with various signs and symptoms of what may well have been HHT, it was Rendu who, in 1896, first reported the combination of telangiectases and hereditary epistaxis as a discrete entity, and one that he distinguished from the more widely known hemophilia (2). In the following decade, a number of reports of this condition appeared, most importantly by Osler (3) and Weber (4), whose names soon joined that of Rendu to form the triple eponymic appellation, that in varying order, has been used by many to label the disease ever since. In 1909, Haynes coined the term hereditary

hemorrhagic telangiectasia for the condition, in recognition of the three features—its hereditary nature, frequent epistaxis, and multiple telangiectases—that by then were thought to characterize it (5).

The remainder of the first half of the twentieth century witnessed numerous case reports, which both reflected and caused somewhat wider medical recognition of HHT; however, the diagnosis was apparently still often not entertained even in the face of “textbook” presentations, and there was relatively little progress in better understanding the condition’s basic underlying biology or in treating it more effectively. In the second half of the twentieth century, several developments began to change this picture—first in terms of therapy, and later in terms of biological understanding. Among major therapeutic advances were the development, starting in the 1950s, of septal dermoplasty for persistent epistaxis by William Saunders and others (6) and the development of transcatheter embolotherapy for pulmonary arteriovenous malformations (PAVMs), starting in the late 1970s, by Robert I. White, Jr, Peter Terry, and others (7). The finding in the 1980s by Bruce Jacobson and others of a patient registry that soon grew into the Hereditary Hemorrhagic Telangiectasia Foundation International provided an impetus for increased patient and provider education, as well for both basic and clinical research.

At the end of the twentieth century, new genetic approaches led to dramatic breakthroughs in understanding of the basic biology of HHT. Over 1000 primary research publications have appeared since 1995. In rapid succession in the mid-1990s, Marchuk, LeTarte and others identified two different causative genes, endoglin (*ENG*) on chromosome 9 and activin-like kinase 1 (*ACVRL1*) on chromosome 12 (see Section 49.2.3) (8,9).

That both genes were involved in the transforming growth factor beta (TGF $\beta$ ) and bone morphogenetic protein (BMP) signaling pathways suggested the biology that lay at the core of the HHT phenotype. That two different genes could cause what had previously appeared to be a single clinical condition raised the question of whether HHT was, in fact, a single clinical entity, or a family of related, phenotypically overlapping conditions.

The 1990s also saw the establishment of forums for communication among the growing international HHT research community, including regular international meetings that advanced both research and clinical collaborations (10,11). The last years of the twentieth century and the first decade of the twenty-first century witnessed other advances, such as the establishment of the first animal (mouse) models for HHT (12–15) and the identification of families segregating features of both juvenile polyposis and HHT due to mutations in SMAD4 (16).

### 49.1.2 Prevalence

Several population-based surveys suggest the prevalence is at least one per 5000–8000 (17). In the County of Fyn, Denmark, the prevalence is 15.6 per 100,000 (18). In the Netherlands Antilles, the prevalence is much higher, 1 per 1331, at least in part due to founder effect in an island population (19). As with many other dominant conditions, age dependency of features contributes to incomplete ascertainment in any family or population-based investigation. No prevalence survey has yet employed molecular diagnosis.

## 49.2 PHENOTYPE AND NATURAL HISTORY

### 49.2.1 Overview

The fundamental problem is in the development of blood vessels, especially the connections between arteries and veins. Problems start in the embryo, but they often do not become clinically important until adulthood. If the tiniest connections, the capillaries, are involved, then the problems involve telangiectases, or 1- to 2 mm enlargements that appear dark red on the skin, the lips, the tongue, or the nasal or the bowel mucosa. Because the telangiectases are close to the surface and have very thin walls, they bleed easily. This accounts for nosebleeds being an early sign of HHT, and gastrointestinal (GI) hemorrhage being a problem in adulthood. When the abnormal connections are larger, they are termed AVMs. The brain, the lung, and the liver are the primary sites of AVMs, but other organs can be involved. The absence of a capillary connection is established early in life, and the individual lesion may or may not expand slowly over many years. An AVM causes problems because capillaries are bypassed. An AVM anywhere results in increased cardiac output, which places strain on the heart. In the lungs, an

AVM provides a direct connection through which bacteria and blood clots in veins can travel directly to the arterial circulation without being filtered by lung capillaries. The result can be a stroke or cerebral abscess if the final resting place is the brain, or ischemic damage to an end organ such as the kidney. Also, pulmonary AVMs provide a shunt that prevents venous blood from being oxygenated, so the partial pressure of oxygen in arterial blood is reduced proportional to the number, size, and location of the lung lesions.

The condition is often misdiagnosed, both because the features vary considerably among those affected (even within a single family), and features accumulate over the lifespan of patients. Formal studies of quality of life show that the clinical complications of HHT, especially epistaxis, have a significant negative impact (20). Both marked inter- and intrafamilial variabilities characterize HHT. Interfamilial variability is due, in part, to different mutations in different genes. Intrafamilial variability is typical of many dominant disorders (21); the precise biology by which it occurs in HHT is still unknown.

**49.2.1.1 Mucocutaneous Telangiectases.** A telangiectasia can appear as a central core with dilated capillaries extending out from it (spider telangiectases) or as a single macular or slightly elevated, more-or-less circular lesion. Spider telangiectases typically occur because of sun exposure or chronic liver disease. Single, circular lesions are typical of HHT. When slight pressure is applied, telangiectases blanch, then quickly refill when the pressure is released. This distinguishes telangiectases from a petechia and an angiokeratoma, which do not blanch, and a cherry angioma, which at best may blanch minimally. In HHT, punctuate telangiectases can appear anywhere on the skin or mucus membranes, but are most common on the fingers, palms, face, lips, buccal cheek, and tongue (Figure 49-1). Microscopy of the nail folds often shows dilated loops between capillaries and can be an early diagnostic sign (22).

Telangiectases may be present in children, but they typically appear later and increase with age. Numerous telangiectases in young children, in the absence of brain or lung AVMs or a family history of HHT, should prompt consideration of other diagnoses, such as ataxia-telangiectasia or benign familial telangiectasia. In adults, cutaneous and oral telangiectases occasionally bleed when traumatized, but they generally are of cosmetic concern only.

Two areas where telangiectases of the mucus membrane pose substantial clinical risk are the nose and the GI tract.

**49.2.1.2 Epistaxis.** Often the first sign of HHT is recurrent bleeding from the nose (epistaxis). Because epistaxis occurs so frequently in the general population, until the episodes become frequent or severe, the patient or parent may not seek medical attention. Even then, the primary care or emergency physician usually treats or refers to the rhinologist but does not delve into the cause. The family

**FIGURE 49-1** Dermal and mucocutaneous features of HHT. A. Digits. B. Ear. C. Lips. D. Tongue.

history of a child that reveals severe epistaxis in close relatives can be the most important piece of evidence that a familial disorder should be entertained, and HHT is at the top of a very short list. Bleeding occurs from mucosal telangiectases and eventually affects about 90% of people with HHT. The average age of onset is 12 years and the average frequency is 18 episodes per month. Nocturnal epistaxis is common. Factors that predispose to bleeding include low atmospheric humidity and digital trauma.

**49.2.1.3 Gastrointestinal.** Bleeding from mucosal telangiectases in any portion of the GI track can lead to chronic anemia. At the most proximal end, lesions on the lips, tongue, and oral mucosa are of cosmetic concern primarily, but bleeding can be annoying and embarrassing. Bleeding from the stomach, small intestine, and colon becomes more common with age; rarely, this is a problem in children or adolescents. Upper and lower endoscopy can reveal the site of blood loss but often shows a myriad of lesions that appear capable of bleeding at any time. Examination of stool for occult blood is of limited use in HHT because swallowed blood from epistaxis yields a positive result.

One uncommon form of HHT is associated with juvenile polyposis and is due to mutations in *SMAD4* (16). Juvenile polyps can bleed or obstruct but are most worrisome because of their susceptibility to malignancy. Mutations in *ENG* can also predispose to juvenile polyps, apparently in the absence of signs of HHT (23). Involvement of both *SMAD4* and *ENG* in both HHT

and polyposis emphasizes the importance of the TGF $\beta$ –BMP signaling pathway in the control of a variety of developmental systems.

**49.2.1.4 Central Nervous System.** Three forms of developmental lesions and one acquired form are common in the brain and spinal column in HHT (24). Telangiectases, venous malformations, and cerebral arteriovenous malformations (CAVMs) are often clinically silent. Their frequency and natural history are unclear because most patients have not been screened adequately or repetitively. Screening by magnetic resonance imaging (MRI) found a 23% prevalence of some cerebral vascular malformation in patients with HHT (25); however, this study also showed that angiography is more sensitive for both detecting and characterizing cerebral lesions. The risk of bleeding from any of these lesions is also unclear; one study suggested a risk of 0.5% per year (26), whereas another found a risk of 1.4–2.0% per year (27). In terms of cerebral hemorrhage of any cause, the risk for a man younger than 45 years of age was 20 times greater in HHT (27). If a malformation is large enough or bleeds, the complications include headache, altered mental status, seizure, and stroke. Migraine-like headaches are of increased frequency especially in those who have an intrapulmonary right-to-left shunt (28,29).

The major acquired lesion is brain abscess, which is thought because of paradoxical embolization of bacteria through a PAVM (30).

**49.2.1.5 Lung.** The single clinical finding that is most likely to prompt consideration of the diagnosis of HHT is the PAVM (Figure 49-2A). It remains uncertain as to what fraction of people with an apparently isolated PAVM actually has HHT. In part, many patients do

**FIGURE 49-2** Filtration function of pulmonary capillary bed and how a pulmonary arteriovenous malformation (PAVM) bypasses that function to produce paradoxical emboli can be envisioned from these renderings. A. Normal capillary bed. (Reprinted with permission from Ref. 139.) B. A simple PAVM. C. A complex, large PAVM. (Reprinted with permission from Ref. 139.)

not undergo detailed screening of the rest of their lungs to detect small lesions. In addition, molecular genetic screening has been available since 2003. PAVMs should be looked for carefully in any person with, or at risk for, HHT, including infants (31), because considerable morbidity results from these lesions. A PAVM of any size can serve as a conduit for bacteria, air bubbles, or clots from the venous circulation to be transmitted directly to the systemic arterial circulation. The risk of cerebral infarction due to embolization is greater in patients with multiple PAVMs (32,33). The PAVM also serves as a right-to-left shunt in terms of oxygenation, and the decrease in arterial  $PO_2$  is generally determined by the size, number, and location of PAVMs. The patient may present with progressively worsening dyspnea on exertion, cyanosis, and clubbing. Polycythemia leading to plethora is uncommon, because most patients with HHT have chronic blood loss from one source or another. Hemoptysis from rupture of a PAVM or bleeding from bronchial telangiectases is not uncommon (~10% over a lifetime), and can be life-threatening when massive (34). Chronic right-to-left shunting can also lead to pulmonary hypertension and failure of the right side of the heart.

Infants and children should be screened for PAVMs since they may have one or more of clinical importance. Typically, however, PAVMs emerge in adolescence and young adulthood. A lesion has a tendency to expand over time, and new ones emerge, which emphasizes the need for life-long assessment. Some young adults will have no evidence of an intrapulmonary shunt, and are unlikely to develop any.

A small fraction of patients with HHT have pulmonary hypertension unrelated to their degree of shunting. These patients typically have a mutation in *ALK1*. Some families with primary pulmonary hypertension but without signs of HHT have mutations in *ALK1* (OMIM 178600; see Chapter 48).

**49.2.1.6 Liver.** Four types of hepatic vascular lesions occur in HHT: (1) telangiectases; (2) direct communication of hepatic arteries to hepatic veins; (3) direct communication of hepatic arteries to portal veins; and (4) portal vein-to-hepatic vein connections (35,36). Several recent surveys using ultrasound, computed tomography (CT), or MRI have shown the frequency of hepatic vascular involvement to be much higher than previously thought, in the range of 40–75% (37,38). Discrepancies in prevalence relate to methods of diagnosis, with CT and MRI being more sensitive than ultrasound and auscultation for a bruit. Angiography is not necessary for routine assessment or screening (36). Hepatic artery-to-hepatic vein shunts place a strain on the circulation and can lead to congestive heart failure. Direct connections between the systemic arterial and portal circulations can cause portal hypertension, splenomegaly, spider-like telangiectases (which are distinct from the telangiectases typical of HHT), and esophageal and hemorrhoidal varices.

Communication between the portal circulation and the systemic venous circulation leads to hepatic encephalopathy, ascites, and an increase in GI hemorrhage. Despite hyperperfusion through the liver, areas of the organ can be relatively ischemic, and areas of fibrosis in a nodular pattern suggest classic cirrhosis (39) or even malignancy. Standard liver function tests are often normal because areas of the liver are relatively spared. Other patients have a pattern suggestive of ischemia in peribiliary regions leading to strictures, bile cysts, increased alkaline phosphatase and, eventually, hyperbilirubinemia (35). Neither percutaneous liver biopsy nor retrograde cholangiopancreatography is usually necessary, and either is of increased risk in HHT.

An HHT referral center in Italy assessed 502 patients for hepatic involvement and found vascular malformations in 154 (40). Followed for a mean of 44 months, 5.2% died of hepatic complications and 25.3% suffered complications. Therapies of various types (discussed in Section 6) successfully treated two-thirds.

**49.2.1.7 Other Manifestations.** Vascular malformations in the kidneys, bladder, retina, and other organs have been reported (41) as has aneurysm of the aorta and coronary arteries (42).

## 49.2.2 Pathology

**49.2.2.1 Gross Pathology.** The fundamental problem is in the development of blood vessels, especially the connections between arteries and veins. Problems start in the embryo, but they often do not become clinically important until adulthood. If the tiniest connections, the capillaries, are involved, then the problems involve telangiectases. Because the cutaneous and mucosal telangiectases are close to the surface and have very thin walls, they bleed easily. This accounts for epistaxis being an early sign of HHT, and GI hemorrhage being a problem in adulthood. A variety of other dysplastic vascular lesions occur, including AVMs. The brain, the lung, and the liver are the primary sites of AVMs, but other organs can be involved. The vascular precursor of an AVM is established early in life, and the individual lesion expands slowly over many years. Other lesions include arterial aneurysms, dilated veins, and complex AVMs with multiple feeding arteries and a mass of channels connecting to multiple veins (Figure 49-2B).

**49.2.2.2 Histology and Ultrastructure.** The absence of capillaries causes dilatation of the postcapillary venule, which is the essence of the punctuate telangiectases.

## 49.2.3 Genetics

The familial nature of HHT was recognized from the earliest descriptions of the phenotype. Inheritance is autosomal dominant with high penetrance if careful phenotypic assessment is performed (41,43). However, considerable intrafamilial variability occurs.

**49.2.3.1 HHT1 and Endoglin (ENG).** Genetic linkage for HHT families was first established to markers on chromosome 9q33–q34 (44,45). Mutations in the gene encoding endoglin were subsequently identified in HHT1 kindreds (9). Endoglin is a homodimeric integral membrane protein expressed at high levels on human vascular endothelial cells of all blood vessels (46). On endothelial cells, endoglin is the most abundant TGF $\beta$ -binding protein (47). The 90 kDa endoglin protein is encoded by a gene comprising 15 exons (48,49). In addition to the originally identified endoglin cDNA, a splice variant was detected called S-endoglin (for short endoglin), coding for an 85 kDa protein (50). The extracellular and transmembrane domains of S-endoglin and the longer endoglin version (L-endoglin) are identical, whereas the alternative splicing creates a novel, 14-amino acid residue cytoplasmic domain for S-endoglin. These two isoforms are coexpressed in different cell types although the majority of the transcripts correspond to L-endoglin. Although the physiologic distinctions between L- and S-endoglin are not yet completely known, in at least two assays of signaling, they differ in their response to ligand (51).

With the advent of large-scale diagnostic mutation analysis for HHT in a number of countries, hundreds of distinct mutations have been identified in the endoglin gene. At the outset, these mutations appeared to be primarily family specific. This led to difficulty in interpreting novel sequence variants, especially putative missense mutations, because each new family harbored a novel mutation that could not be cross-referenced with a previously described mutation. With the great number of mutations now identified and cataloged in databases, recurrence of the same mutation in apparently unrelated families is slightly more common. Nonetheless, novel sequence variants continue to predominate. In this context, cross-reference to normal sequence polymorphisms identified in the appropriate population helps to identify those alterations that merely represent normal sequence polymorphisms.

Mutations thus far identified in the endoglin gene include missense mutations, nonsense mutations, splice-site changes, and small nucleotide insertions and deletions leading to frameshifts and premature stop codons, all found throughout most of the exons of the gene. Expression data from a number of frameshift and nonsense mutations show that many of these create unstable messages (48,52), and therefore, little to no mutant proteins would be produced. Thus, these mutations would create null alleles. Other clear examples of null alleles include large deletions, duplications, and other genomic rearrangements involving multiple exons of the gene. All genetic testing centers for HHT now routinely search for such genomic rearrangements, and one center recommends that the search for DNA sequence variants and genomic rearrangements should occur simultaneously, rather than sequentially, to ensure identification of all possible mutations in the genes (53). Larger genomic mutations contribute to at least some of the

approximately 20% of HHT cases, in which no mutation can be identified in *ENG*, *ACVRL1* or *SMAD4*.

**49.2.3.2 HHT2 and ALK1 (*ACVRL1*).** A second HHT locus (HHT2; OMIM 600376) was identified in the pericentromeric region of chromosome 12 (8). A potential candidate gene, *ACVRL1*, encoding the ALK1 protein (activin receptor-like kinase 1), was shown to map within this interval, and mutations were identified within this gene in HHT2 families (8).

ALK1 protein is expressed primarily on endothelial cells and in highly vascularized tissues. Studies using a reporter gene trap within the mouse *alk1* gene suggest that its transcript is expressed most highly, and possibly exclusively, in the arterial endothelium (49,54). By sequence homology, ALK1 had been considered a type I cell surface receptor for the TGF $\beta$  superfamily of ligands. Until recently, however, the authentic ligand that activated ALK1 was unknown. Two groups independently demonstrated that BMP9 and the related BMP10 could specifically activate ALK1 (55,56). Subsequent studies have confirmed the critical role of BMP9/ALK1 signaling in angiogenesis. Most data support a role for ALK1/BMP9 signaling in inhibition of angiogenesis (55–58), whereas one study concluded that this pair stimulates angiogenesis (59). These discordant results may be due to the use of different endothelial cell subtypes in each study (59) since the specific response to the signal might be modulated by the differential expression of any one of several different type II coreceptors in an endothelial cell subtype-specific manner (58). Regardless, the discovery of BMP9 as a ligand for ALK1 has spawned a new avenue of research to determine whether HHT is caused by a defect in TGF $\beta$  signaling, BMP9 signaling, or an imbalance between the two.

Human *ACVRL1* contains 10 exons, nine of which encode the protein sequence (60). With large-scale mutation screening being performed worldwide in HHT families, hundreds of mutations have been identified in *ACVRL1*. Mutations in *ACVRL1*, similar to those in *ENG*, are for the most part family specific, again leading to difficulties of confirmation by cross-referencing with previously described mutations. Careful cataloging of normal sequence variants will help in sorting out mutations from population polymorphisms.

Mutations are found throughout the gene and fall into classes of nonsense, frameshift, splice-site, and missense mutations. Genomic rearrangements of *ACVRL1* are also found, and tests for such genomic mutations are now routinely included in genetic testing for HHT. Overall, missense mutations in *ACVRL1* appear to be more common than in endoglin. RNA expression data for some of the *ACVRL1* nonsense and frameshift mutations show that little or no message can be detected from the mutant allele (60). These data, in combination with the sum of the mutation data, demonstrate that most mutations create null alleles, which should lead to reduced signaling through the ALK1 receptor. Reduced signaling capacity

has been validated now for representative *ACVRL1* missense mutations (61). These authors developed the first functional assay for ALK1 signaling based on the discovery of BMP9 as the specific ligand for the receptor (61). Previously identified missense mutations in *ACVRL1* all showed defective BMP9 signaling, whereas known coding polymorphisms did not affect receptor function. Significantly, missense variants of uncertain significance could now be functionally categorized as either mutations or benign polymorphisms, demonstrating the utility of their signaling assay as a tool to inform DNA-based diagnostics.

**49.2.3.3 HHT3.** Evidence for a third locus and gene for HHT (HHT3; OMIM 601101) was provided by a single HHT family (62) that was unlinked to both the HHT1 and HHT2 loci. The locus in this family and in an additional smaller family was mapped to chromosome 5q31–q32 (63). Higher resolution mapping has further narrowed the candidate interval to a 5.7 Mb interval (64). The gene has yet to be identified, but no previously known receptor or effector for TGF $\beta$ /BMP signaling maps within the revised interval. The eventual identification of this gene is likely to shed new light on HHT pathogenesis, by either disclosing the identity of a heretofore unknown factor in TGF $\beta$ /BMP signaling, or by uncovering an unrelated, but parallel signaling pathway leading to the same clinical phenotype. The prevalence of HHT3 also remains uncertain, because to date, only two HHT families have shown statistically significant linkage to this region. Nonetheless, HHT in some of the families negative for mutations in *ENG*, *ACVRL1*, and *SMAD4* that have confounded diagnostic DNA testing laboratories will likely be shown to be due to mutations in this novel HHT3 gene.

**49.2.3.4 HHT4.** Evidence for a fourth locus and gene for HHT (HHT4; OMIM 61055) was provided by a single, large HHT family that maps to chromosome 7p14 (65). An obvious candidate gene mapping within the interval, bone morphogenetic protein endothelial receptor (BMPER), was ruled out early on by DNA sequence analysis. Loss-of-function BMPER mutations were subsequently identified in an autosomal recessive, perinatal lethal skeletal disorder diaphanospondylodysostosis (66). The HHT4 gene has yet to be identified but since there are no other obvious biological candidate genes mapping within the interval, its discovery should also prove invaluable to our understanding of HHT pathogenesis. As with HHT3, the prevalence of HHT4 remains unknown, but at least some of the families negative for mutations in *ENG*, *ACVRL1* and *SMAD4* will likely be shown to be due to mutations in this novel HHT4 gene.

**49.2.3.5 Juvenile Polyposis–HHT: A Syndromic HHT Phenotype (OMIM 175050).** A number of case reports suggested an association of juvenile polyposis (JP) and HHT, or with one or more features of HHT, especially, PAVMs (67–71). One of the two genes mutated in JP is *SMAD4*, encoding the Smad4 protein, a downstream effector of TGF $\beta$  signaling. The other gene mutated in JP is *BMPRIA*, encoding a type I receptor for another

ligand in the TGF $\beta$  superfamily (72). It is now known that most patients with JP harboring an *SMAD4* mutation display a combined syndrome of juvenile polyps and HHT (16,73). Careful clinical screening for both GI polyps and the various vascular malformations associated with HHT has shown that affected individuals meet diagnostic criterion for both JP and HHT (16). The combined syndromic phenotype is estimated to occur in 15–22% of individuals with an *SMAD4* mutation (74), but this may be an underestimate because of a lack of recognition of the HHT phenotype in individuals with clinically silent vascular phenotypes.

Thus far, only mutations in the *SMAD4* gene have been identified in JP–HHT syndrome. The mutations tend to cluster in the carboxyl terminal of the *SMAD4* protein, particularly in the MH2 domain. However, the majority of *SMAD4* mutations previously described in JP also cluster in the same region, ruling out a clear genotype:phenotype correlation. The molecular analysis of a larger number of JP–HHT cases shows that mutations throughout the *SMAD4* gene can cause the syndrome (75). Therefore, any patient who tests positive for an *SMAD4* mutation is at risk for the combined syndrome of JP–HHT, and should be monitored accordingly. Although JP–HHT cases are usually first identified as JP patients, some individuals may first present with the HHT phenotype. Of 30 patients with HHT and no clinical evidence of JP, who were negative for mutations in *ENG* and *ALK1*, screening for mutations in *SMAD4* found three positive (76). These *SMAD4*-positive patients should be screened intensively for polyps. The determination of the true penetrance of JP–HHT syndrome in *SMAD4* mutation carriers requires clinical screening of all JP patients (harboring any *SMAD4* germline mutation) for HHT-associated phenotypes.

Because patients with these two disorders are generally ascertained through distinct medical specialties, genetic testing is recommended for patients presenting with either phenotype to identify those at risk of this syndrome. In particular, patients with juvenile polyps who harbor an *SMAD4* mutation should be screened for the presence of vascular lesions associated with HHT, especially occult AVMs in visceral organs that may otherwise present suddenly with serious medical consequences.

## 49.3 ETIOLOGY

### 49.3.1 Molecular Pathology

**49.3.1.1 Genotype–phenotype Correlations in HHT.** Large-scale DNA sequencing for diagnostics in multiple countries and populations has provided a few consensus genotype–phenotype correlations in HHT. These correlations can be valuable in genetic counseling and in establishment of guidelines for routine medical care and screening for HHT patients. Although one study found that truncating mutations in the endoglin gene are

associated with a more severe outcome than missense mutations (77), and another suggested that truncating mutations in *ALK1* were associated with a higher frequency of epistaxis and telangiectasia (78), in general, mutation-specific genotype–phenotype correlations have not been uniform in all populations. There seems to be limited utility in using the nature of the germline mutation to predict clinical outcomes. This is perhaps not surprising, because the variability in clinical presentation among family members harboring the same mutation can be as broad as the variability among different families each with a distinct mutation.

The variability among family members with the same germline mutation suggests that yet undiscovered biological (such as hormonal), environmental, genetic and epigenetic factors influence the clinical presentation of HHT. Evidence for the role of other genes in modulating the phenotype comes from genetically engineered mutant mouse strains. The phenotype of mice with an engineered mutation in the murine endoglin gene is heavily influenced by the genetic background (that is, the particular inbred lineage) of the mice (79). Similarly, mice lacking the TGF $\beta$ 1 ligand show profound differences in the resulting phenotype depending on inbred strain background carrying the deleted allele. The strain-specific differences for the loss of TGF $\beta$ 1 have been exploited to map multiple chromosomal loci that modify the resulting phenotype (80–82). However, the genes underlying these modifier loci have yet to be identified in the mouse, and thus, the human orthologs cannot yet be investigated as potential modifiers of the human HHT phenotype.

There is, however, clear evidence for a correlation between the incidence of various clinical manifestations of HHT and the particular gene mutated. An initial subjective observation was made that the families that were linked to HHT1 (endoglin) seemed to have a much higher incidence of PAVMs reported than families for whom this locus was excluded (21,43). Further analysis confirmed that this difference was genuine (83–85). However, these initial results were interpreted with caution because they relied on incomplete screening for the pulmonary AVMs, such that only patients with symptomatic pulmonary lesions were scored positive for these lesions. Multiple large studies have now confirmed that patients with endoglin mutations exhibit anywhere from a twofold to up to a 10-fold higher incidence of PAVMs than patients with *ALK1* mutations (78,86–88).

Some of the variabilities observed among studies are likely due to differing ascertainment biases for the pulmonary phenotype. Similarly, cerebral AVMs are also more common in patients with endoglin mutations than those with *ALK1* mutations, and in some studies, appear to be almost exclusively found in HHT1 patients (86,88). One study found neurological complications secondary to cAVMs and pAVMs only in HHT1 patients (88).

In comparison to HHT1, HHT2 patients (*ALK1* mutation) more commonly exhibit gastrointestinal bleeding

(78) and show a higher frequency of hepatic AVMs (78,83,86,88,89), with two studies observing severe or symptomatic hepatic disease only in HHT2 (78,88). HHT2 is also associated with an increased risk to develop pulmonary hypertension (89–93). Pulmonary hypertension has also been observed in HHT1 cases (94–97).

Despite the wealth of genotype:phenotype data that has emerged since 2007, the establishment of correlations such as these continue to be fraught with difficulties due to ascertainment bias. Unless each family member is carefully and consistently screened using the same modality and for the entire spectrum of clinical manifestations regardless of current clinical presentation, these correlations will continue to be incomplete. The best data have come from the more recently published studies from large HHT centers of excellence, where comprehensive clinical screening was coordinated with molecular diagnostics. But even these more robust estimates of the incidence of clinical phenotypes should be used cautiously because these different incidence rates merely represent averages over large numbers of patients. Numerous individual cases are known that would violate the averages, and negligence in screening for any of the visceral manifestations associated with HHT could result later in serious medical consequences for the patient.

## 49.4 PATHOGENESIS

### 49.4.1 Animal Models

The roles of the genes encoding endoglin and ALK1 in vascular development have also been probed by disruption of these genes in the mouse. Homozygous disruption of either genes in the mouse results in embryonic lethality because of arrested endothelial remodeling. Three different groups have disrupted the endoglin gene (12–14). The primary defect is the maturation arrest of the primitive vascular plexus of the yolk sac into defined vessels, leading to channel dilation and rupture. Embryos show distended blood yolk sac vessels by E9.5, a lack of vascular organization by E10.5, and embryos are resorbed by E11.5. Smooth muscle cell differentiation and recruitment to the vessels is also defective. Various heart defects have been reported, including abnormal cardiac looping, and enlarged cardiac ventricles and pericardial sac. Heart valve formation is also disrupted, with reduction in the size of the atrioventricular endocardial cushions and disorganization of the endothelial surface of the cushions. Thus, endoglin plays a crucial role in the heart development. Careful analysis of endoglin null mice shows that they can develop AVMs during the embryonic stage (98). These data suggest a very early defect in the maintenance of arteriovenous vascular beds.

Embryos homozygous for null *alk1* mutations die *in utero* because of the defects in vascular development (99,100). By E9.5, they show absence of mature blood vessels in the yolk sac, and the embryos are resorbed

by E10.5. Histological analysis of the mutant embryos shows excessive fusion of capillary plexus into cavernous vessels. Hyperdilation of large vessels and deficient differentiation and recruitment of smooth muscle cells are also evident. The endocardium and myocardium are also immature, suggesting a role for ALK1 in heart development.

ALK1 function *in vivo* has also been probed using the powerful zebrafish (*Danio rerio*) experimental system. A germline mutation in the zebrafish *ALK1* orthologous gene (*acvrl1*) or morpholino knockdown of its transcript results in dilated cranial vessels because of an increased number of endothelial cells (101). The increase in endothelial cell number in the *acvrl1*-mutant fish is consistent with the majority of cell signaling studies that find that ALK1/BMP9 signaling inhibits angiogenesis. The zebrafish system has also been exploited to investigate the *in vivo* effects of *ALK1* mutations found in HHT2 patients (102), and to explore the phenotypic consequence of loss of TAK1, a downstream kinase that is activated by ALK1 (103). Loss of TAK1 in the zebrafish mirrors the ALK1-mutant phenotype, and TAK1 overexpression can rescue the animals from the phenotypic consequences of loss of ALK1. Morpholino knockdown of both ALK1 and TAK1 shows a synergistic effect on the vascular phenotype. These combined data suggest that *TAK1* might be a novel HHT gene, or possibly a genetic modifier of the clinical phenotype.

In mice heterozygous for both *ENG* and *ALK1* knockouts, the proper genetic model for the HHT phenotype shows that an HHT-related phenotype will develop over time. Lesions such as cutaneous or mucocutaneous telangiectasias as well as visceral AVMs are observed and these resemble the lesions seen in human patients (13,79,104–106). Detailed immunohistochemical characterization of the vessels of mice heterozygous for a mutation in endoglin has led to the hypothesis that HHT involves a generalized vascular abnormality that includes dilated postcapillary venules, vascular walls lacking smooth muscle cells, and irregular collagen and elastin staining (106). Bleeding was associated with regions of inflammation, which may provide a clue to therapy for the bleeding associated with the human patients.

The endoglin mouse model has been used to investigate the earliest events in the pathogenesis of HHT-associated vascular dysplasia. In addition to its role in TGFβ signaling, the mouse models have uncovered a role for endoglin in the regulation of vascular tone. Resistance arteries from *Eng*<sup>+/-</sup> mice display an endothelial nitric oxide synthase (eNOS)-dependent dilation and impairment of the myogenic response (107). Endoglin physically associates with eNOS (107) and also regulates eNOS expression at the transcriptional level via Smad2-dependent TGFβ signaling (108). Endoglin-deficient endothelial cells exhibit uncoupled eNOS activity, producing less NO, and instead generating more eNOS-derived superoxide (107). Intriguingly, the uncoupled activity was not observed in the lungs of newborn *Eng*<sup>+/-</sup> mice, but increased as the

mice aged to adulthood (109). This age-dependent eNOS uncoupling correlated with vasorelaxation in the adult mice, and may explain the development of the pulmonary lesions in adolescents with HHT.

The data from the *Eng*<sup>+/−</sup> mice also suggest a molecular explanation for the association of HHT with pulmonary hypertension. The HHT1 mouse model exhibits increased right ventricular systolic pressure, degeneration of the distal pulmonary vasculature, and muscularization of the small arteries of the lung, each of which can be attributed to uncoupled eNOS activity (110).

These physiologic analyses of the blood vessels in HHT mouse models have helped to elucidate the underlying pathogenesis of HHT. These models suggest that even the “normal” (nonlesional) vessels in HHT harbor an intrinsic structural or physiological defect. The connection with vasodilation, the myogenic response, and nitric oxide levels has provided novel and testable hypotheses concerning the nature of the initiation events leading to vascular lesion development. Increased superoxide may create endothelial cell damage, and this may be an important clue to the initiation of vascular lesion development.

Although the mechanisms whereby endoglin and ALK1 affect TGF $\beta$  signaling pathways are rapidly coming into focus, their specific roles in modulating vascular endothelial and smooth muscle cell properties are just beginning to be elucidated. Despite these positive signs, the specific factor or factors responsible for vascular lesion formation remain unknown. A reduction to 50% of functional endoglin or ALK1 levels is compatible with development of a normal vascular system *in utero* since there is no evidence of increased miscarriage in HHT families. Yet mutation carriers are at nearly 100% risk of developing the vascular lesions observed in HHT. The vascular lesions in HHT are localized to discrete regions within specific organs in the affected tissue, with little evidence of pathology outside the lesions themselves. This suggests that some genetic, physiological, or mechanical event initiates the formation of each vascular lesion. The pathobiology of the disease may be related to remodeling of the vascular endothelium following an unknown initiating event. TGF $\beta$ 1 mediates vascular remodeling through effects on extracellular matrix production by endothelial cells, stromal interstitial cells, smooth muscle cells, and pericytes. Perturbations in the TGF $\beta$  signaling pathway in HHT may lead to altered repair of vascular endothelium and remodeling of the vascular tissue via changes in expression profiles of extracellular matrix proteins. Continued clinical research on this disorder, in combination with studies of animal models and basic biochemical characterization of the signaling pathways involved, will play an important role in elucidating the pathogenesis of HHT.

## 49.5 DIAGNOSIS

Until very recently, the diagnosis of HHT could only be made on clinical grounds. However, with the

clinical availability of DNA-based genetic testing, this has changed. In some situations, when signs, symptoms, and/or family history raise the possibility of HHT, genetic testing can now provide a definitive answer. However, because of technical challenges, including that HHT can be due to a mutation in any one of several genes, and that most families tested to date have had unique mutations, genetic testing is not always currently simple or definitive. Genetic testing is particularly helpful when the “familial” mutation has been identified; in such cases, presence or absence of the mutation, and thus of affected status, in other family members can usually be readily determined. In other situations, clinical grounds remain the mainstay for making the diagnosis. Investigators in Canada compared the use of molecular diagnosis for identifying which relatives in an HHT family were affected, and then performing clinical screening only in those who test positive, with the current protocol of performing clinical screening of every relative at risk (111). From a cost perspective, based on expenses incurred for both molecular and clinical testing in Canada, traditional clinical screening was 50% more expensive. A similar study was conducted in the USA, where many health economic issues are quite different from Canada (112). However, the conclusion that molecular genetic screening of at-risk relatives is highly cost effective was affirmed. These results may not be generalized to countries with substantially different cost structures for the various tests.

The classic findings in HHT are the quadrad of recurrent epistaxis, multiple telangiectasias, visceral AVMs, and a positive family history. However, clinical diagnosis can be challenging, especially because many patients with HHT do not show evidence of all features and recurrent epistaxis (as an isolated finding or an indication of an underlining bleeding diathesis, such as von Willebrand disease) and, to a lesser extent, multiple telangiectasias (as an isolated finding, or due to CREST syndrome, ataxia–telangiectasia, hereditary benign telangiectasia, chronic liver disease, or pregnancy) are each common findings in the general population. However, when the full triad of recurrent epistaxis, multiple telangiectasias, and family history is present, the diagnosis of HHT is both straightforward and rarely incorrect.

The presence of such characteristic visceral lesions as AVMs can also be a key to clinical diagnosis, particularly PAVMs, because a majority of those with a pulmonary AVM prove to have HHT (this is especially true if there are multiple PAVMs). Similarly, GI telangiectasias are often, but not always, a sign of HHT. Indeed, any individual with pulmonary, cerebral, hepatic, or spinal AVMs or GI telangiectases should be evaluated for the possibility of having HHT.

Perhaps the most useful framework for making the diagnosis of HHT on clinical grounds is the so-called Curacao criteria, devised by a number of clinicians from

around the world experienced in the disorder (11). The four criteria in this construct are as follows:

- Epistaxis
- Multiple telangiectasias at characteristic sites (lips, oral cavity, fingers, nose)
- Visceral lesions (such as GI telangiectasias or pulmonary, cerebral, hepatic, or spinal AVMs)
- Family history of a first-degree relative with HHT according to these criteria.

The diagnosis of HHT is believed to be definite if three or four of these criteria are present, possible if two are present, and unlikely if fewer than two criteria are present. The authors of the Curacao criteria also noted that “Within HHT families, a firm diagnosis can be made on the basis of two separate visceral manifestations, though this is not applicable to the general population” (11).

## 49.6 MANAGEMENT

### 49.6.1 Mucocutaneous Telangiectasias

Lesions on the tongue, lips, and fingers may bleed when traumatized. Photocoagulation with a laser can be effective in stopping acute bleeding. Smaller lesions can be eliminated, and this is of some cosmetic utility around the face.

### 49.6.2 Epistaxis

Often the most frustrating and debilitating feature of HHT is recurrent bleeding from the nose. Bleeding often starts spontaneously, even during sleep, and can be profuse. The unpredictability of epistaxis and the difficulty in stemming the acute hemorrhage may severely affect a patient’s occupation, social interactions, and activities. Local pressure by pinching the bridge of the nose is obviously the first maneuver, but the actual telangiectasias that is bleeding may be so proximal as to not be compressible externally. Various devices have been used for internal compression of nares. Some have been designed by patients, whereas others (such as Foley catheters, with the balloon providing tamponade) have gained currency in emergency departments. None is routinely efficacious, and some carry risks. Typically, the clot will be dislodged when the gauze or device is removed. Prolonged pressure on the mucosal surface can cause ischemia or infarction. Cauterizing agents, such as silver nitrate, may be useful for an initial, small bleed, but are useless for large ones. Angiographic procedures to localize the feeding artery and embolize it are fraught with hazards, especially necrosis of nasal tissue or ischemia of the vascular supply to the eye. The combined septenopalatine and ethmoid arteries supply about two-thirds of the blood to the septum; occluding one or both leads to collateral formation within a few months.

Once the acute event ends, endoscopic examination of the nares typically reveals many telangiectasias, and the ones most likely to bleed can be treated with laser phototherapy. A variety of wavelengths have been studied, and rhinologists often have their favorite instruments. Some patients achieve long-term improvement from periodic photocoagulation. However, those who continue to bleed enough to require transfusion of packed erythrocytes on a regular basis need to be considered for septal dermoplasty. In this major procedure, the inferior turbinate is resected and a skin autograft is placed by suturing to the septum superiorly and then packing the nose (113). After several weeks, the graft adheres to the nasal mucosa and often provides relief for several years. Unfortunately, telangiectases eventually can appear on the surface of the graft and lead to renewed epistaxis. Additionally, the grafted skin must be kept moist and can be a site of bacterial overgrowth.

Prevention of epistaxis, although imperfect, is important to practice. The goals in severe cases should be to reduce or eliminate the need for visits to emergency rooms, reduce or eliminate the need for transfusions, and improve the quality of life. The ambient humidity should be kept as high as feasible. Allergies should be controlled to the extent possible and airborne irritants, such as cigarette smoke, should be excluded. Spraying the nares with dilute saline or carefully applying an emollient such as petroleum jelly reduces crusting. Various medications, including hormones and antifibrinolytics, have also been useful in selected patients, but all have important risks and contraindications (114–116). Local or systemic agents that produce vasoconstriction can be beneficial in the short term, but they cause a rebound inflammation in the nasal mucosa that is counterproductive. Several agents have been reported to be effective in reducing severe epistaxis in individual patients or small, nonrandomized series. The anti-VEGF drug, bevacizumab, given topically or systemically, holds promise (117,118) but can be associated with severe adverse effects. Thalidomide and tranexamic acid also being studied more systematically, now that case reports and small series demonstrating encouraging results have appeared (119).

Drugs that alter platelet function, such as aspirin and nonsteroidal anti-inflammatory agents, should be avoided. However, if a patient with HHT develops a clinical problem that requires systemic anticoagulation, such as atrial fibrillation or deep venous thrombosis, then warfarin can be used with attention to keeping the INR in the low end of the therapeutic range. There is as yet no experience in HHT with the newer oral anticoagulants such as inhibitors of thrombin or Factor Xa.

### 49.6.3 Central Nervous System

Vascular malformations present at birth are usually asymptomatic, but large venous malformations and CAVMs, in the absence of bleeding, may cause problems

because of their size or location. Whether any particular lesion needs to be treated by radiation, surgery, or vascular occlusion needs to be considered on the basis of the patient's symptoms and age (26,120).

Brain abscess, due to paradoxical embolization of bacteria through a PAVM, needs to be treated in several ways. First, based on the neurologic and general health status, a decision about drainage and antibiotics must be made. Second, further central nervous system (CNS) embolization must be minimized by treating all sources of right-to-left shunts. Just because PAVMs are the most likely culprit in HHT, the presence of a patent foramen ovale or atrial septal defect should not be overlooked.

Because of the risk of CNS embolization in HHT, particular care must be paid to any instance when bacteria or air might enter the blood stream. All people with HHT should adhere to routine prophylaxis against endocarditis. Additionally, all intravenous lines, except for the infusion of blood or radiographic contrast, should have special filters to prevent air bubbles from entering the vein.

#### 49.6.4 Lung

Plain chest radiography, pulse oximetry, arterial blood gases, or a combination thereof are insensitive for detecting all but major right-to-left shunts in the lung. The contrast echocardiogram, in which agitated saline is injected into an antecubital vein as the four-chambered view of the heart is observed, is a useful screening tool for PAVMs (121). In the normal situation, the microbubbles are absorbed in the lung capillaries and do not appear in the left atrium. Appearance of contrast ("bubbles" in common parlance, but not of a size to endanger the CNS) in the left atrium immediately (i.e. one to three heart beats) after it enters the right side of the heart strongly suggests a septal defect, typically a patent foramen ovale. If this occurs, then a pulmonary shunt cannot be diagnosed, and the patient must have a CT scan. If contrast does not appear for four to eight heart beats, then there is likely a shunt in the pulmonary circulation. However, a few percent of "normal" individuals will have delayed passage of a few bubbles (122,123). Whether this represents a "false positive" or the presence of small and clinically irrelevant intrapulmonary shunts is unclear. Quantity of the contrast in the left atrium is a rough guide to the number and size of the PAVMs. Delayed appearance of more than a few bubbles requires follow-up imaging.

The standard protocol to address the size, number, and location of PAVMs is a high-resolution CT scan of the lung before and after injection of radio-opaque contrast. The ability to reformat the images is especially useful to distinguish potential PAVMs from lung nodules of various types and to define the number and size of the feeding arteries and the draining veins.

Until the early 1980s, patients with a PAVM of any cause were not treated unless they had recurrent

hemoptysis, severe arterial desaturation, or high-output heart failure. Then, the segment or segments of lung with the offending or largest PAVMs were resected. Unfortunately, because PAVMs in HHT can progress over time, this surgical approach could be used only a limited number of times. Robert White, a radiologist, and Peter Terry, a pulmonologist, at Johns Hopkins Hospital developed the ability to occlude PAVMs by means of balloons inserted into the feeding artery and then filled with saline containing radio-opaque dye (124,125). This approach, since modified to involve wire coils that invoke a thrombus in the feeding artery, has revolutionized the management of the lung in HHT. Now, under fluoroscopic guidance, four to six or more PAVMs can be treated in one session (Figure 49-3). Complications include pleuritic chest pain that typically resolves in a few days, failure to occlude feeder vessels completely (more common in complex AVMs or when a feeding artery is large), transient ischemic episode, rare paradoxical embolization of a device, and recanalization (126–128).

Until recently, PAVMs with feeding arteries of <3 mm diameter were left untreated. However, some episodes of cerebral embolization occurred (129), and we and others now recommend occluding any PAVM that can be reached by a catheter. This aggressive approach requires an expert interventional radiologist who has considerable experience with HHT. After all PAVMs that can be occluded are, the patient should have a repeat CT scan in 6 months to document that all remain occluded (i.e. that no recanalization has occurred). Subsequently, a CT scan should be performed every five years to monitor emergence or growth of any additional lesions (Figure 49-4).

Major complications related to PAVMs can occur during pregnancy and in the postpartum period due to pulmonary hemorrhage, increased right-to-left shunting, or cerebrovascular events (130). Any patient diagnosed with HHT during pregnancy should undergo high-resolution CT of the lung with contrast. Embolotherapy is indicated during pregnancy for PAVMs that can be reached by an intervention catheter (131).

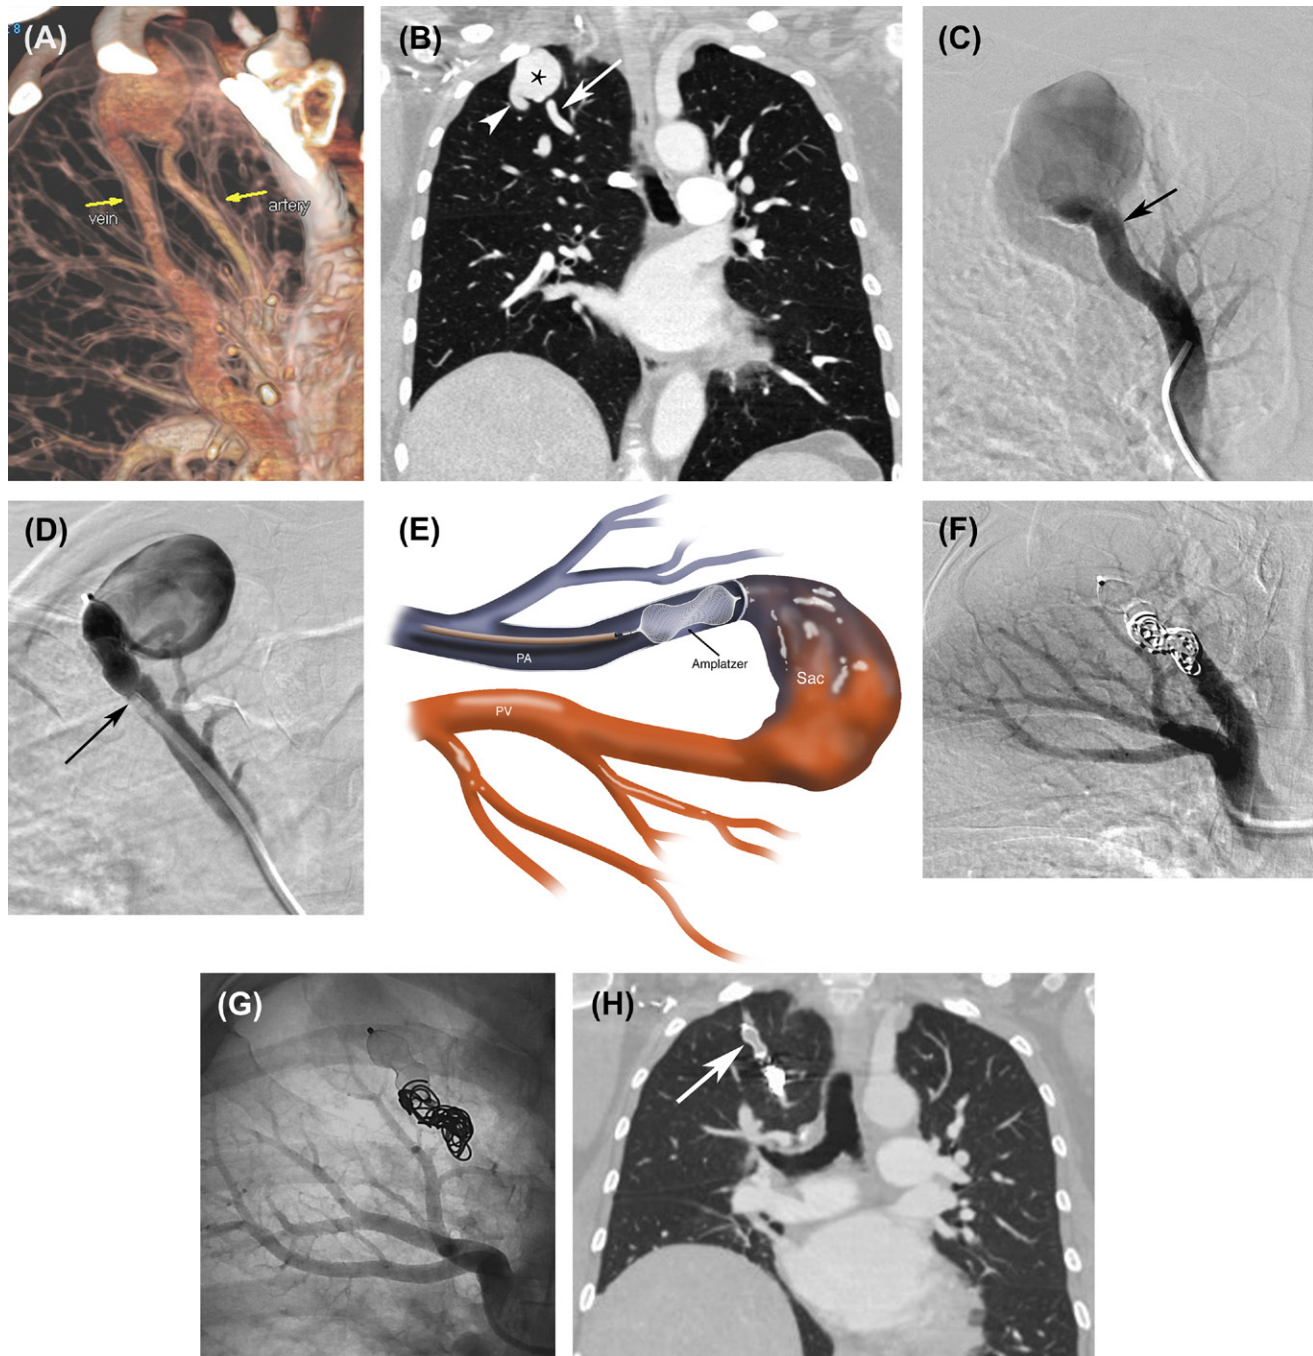

#### 49.6.5 Liver

Vascular lesions in the liver are much less amenable to treatment than are PAVMs. Occlusion of the feeding vessel or vessels, although technically feasible, carries an unacceptable risk of infarction of substantial regions of liver parenchyma. There also is an increased risk of infection associated with endoscopic retrograde cannulation of the pancreas, so ERCP is contraindicated in HHT.

Patients who have hepatic encephalopathy can be treated with nitrogen restriction and lactulose. Those with high-output cardiac failure respond initially to diuretics.

The therapy of last resort is liver transplantation. Unfortunately, because tests of liver function often

**FIGURE 49-3** Fifty-two-year-old woman with known right upper lobe PAVM. Patient was followed for 14 years at another institution and told treatment was not needed. She has obvious HHT with a strong family history, epistaxis, and telangiectases, and was known by her primary care physician to have HHT. She was asymptomatic. A. Color-enhanced coronal reconstruction from CT shows simple PAVM in the right upper lobe; feeding artery and draining vein are labeled. Feeding artery measured 12 mm in diameter. B. Representative image showing feeding artery (arrow), sac (asterisk), and draining vein (arrowhead). C. Image from selective right upper lobe pulmonary angiography confirms simple angio-architecture; the feeding artery is indicated. D. Image obtained during contrast injection with 16 mm Amplatzer vascular occluder deployed at the mouth of PAVM sac. Arrow shows occluder still attached to delivery cable. E. Diagrammatic representation of panel D. F and G. Subtracted (F) and unsubtracted (G) postembolization pulmonary arteriograms after placement of coils in addition to Amplatzer vascular occluder show occlusion of PAVM. H. Representative image from coronal CT reconstruction 6 months after embolization. Sac has almost completely disappeared. Characteristic appearance of Amplatzer device (arrow). Patient reported marked improvement in her exercise tolerance. (*Reprinted with permission from Ref. 139.*)

remain relatively normal despite severe vascular disease in the liver, patients have difficulty gaining access to the transplant list. One report found vascular dilatation in the allografts of two patients of 8 and 10 years

following transplant; whether these findings were in some way related to the underlying HHT, and if so, how common and important this issue will remain to be studied (116).

**FIGURE 49-4** Multiple, treated and untreated PAVMs in one lung. (Reprinted with permission from Ref. 139.)

### 49.6.6 Gastrointestinal

Hemorrhage from the GI tract can be one of the most debilitating and frustrating problems of HHT, especially in older people. There is no good way to monitor chronic bleeding. Testing the stool for occult blood is useless because most patients swallow blood from bouts of epistaxis, which turns the test positive. Patients should monitor their bowel movements for signs of moderate GI bleeding (e.g. tarry stools). However, most patients who become anemic have mild, chronic bleeding that escapes their attention. Upper and lower endoscopy typically shows multiple mucosal telangiectasias from the oral cavity to the duodenum and from the rectum to the ileocecal valve. The number of telangiectasias roughly correlates with the anemia and transfusion requirement (132). Any lesion that appears to be bleeding can be cauterized. However, there is no point in attempting to treat every telangiectasia, especially if repeated endoscopies are contemplated. Capsule endoscopy confirms that telangiectasias exist throughout the jejunum and ileum; but push enterostomy or major surgery are rarely required (133). As with refractory epistaxis, hormonal (estrogen/progesterone in women without contraindications, and danazol in men) and antifibrinolytic therapy may have a role in chronic GI bleeding (132,134). Similarly, experimental agents such as thalidomide and bevacizumab are worth studying (118,119). Selective mesenteric arteriography can reveal intestinal AVMs that can be embolized

(135) but the site or sites of chronic blood loss usually remain obscure.

### 49.6.7 Anemia

Unless a contraindication exists, virtually all adults with HHT should take supplemental iron. The amount and form of iron depend on the severity of the anemia (136). Oral iron can produce adverse effects including constipation and nausea. Patients who do not tolerate oral iron supplements or do not absorb iron from the intestine (e.g. celiac disease) need intravenous iron. All preparations can produce allergic reactions. Those with lower iron content can be infused faster with less risk of adverse effects; however, multiple infusions are necessary. Those with higher iron content must be infused slower, but if successful, may replete stores with one dose. Additional cofactors, folate, and B12 should be considered. Inability to replete iron stores due to severe blood loss despite iron supplementation requires episodic or even regular transfusions of packed erythrocytes. Any person being treated for anemia should have periodic assessment of blood counts and iron stores.

### 49.6.8 Counseling

The same issues that arise in most serious autosomal dominant disorders occur in HHT. The recent availability of molecular diagnosis offers promise of presymptomatic and prenatal diagnosis. However, complexities often arise because of intergenic heterogeneity, “negative” results, and DNA sequence variants of uncertain pathogenic importance (137).

The Hereditary Hemorrhagic Telangiectasia Foundation International ([www.hht.org](http://www.hht.org)) plays an important role in several areas. The organization facilitates the establishment of centers at academic hospitals that provide comprehensive medical and counseling services for patients and families with HHT. There are now 33 centers worldwide, including 15 in North America. The Foundation also sponsors national conferences for patient education and support, and biennial international research symposia.

### 49.6.9 Life Expectancy

Infants and children with HHT and unusually severe vascular malformations in the CNS or lung can die. Many adults with HHT live into their eighth and ninth decade despite severe anemia from epistaxis and GI bleeding. In 1999, a mortality analysis of patients in one county in Denmark showed that patients younger than age 60 died at twice the rate of the population average (18). A more recent study from an HHT center in Italy confirmed an increased peak in mortality rate in patients under the age of 50 years, and somewhat higher mortality in those ages 60–79 (138). Life expectancy was not related to gender or to genotype.

## ACKNOWLEDGMENTS

This revision was accomplished during a time of support for REP by the National Heart, lung and Blood Institute (GenTAC) and the National Human Genome Research Center (Center of Excellence in ELSI Research P50-HG-004487), both of the U.S. National Institutes of Health, and while in residence at the Brocher Foundation, Hermance, Switzerland. We also thank all of our colleagues who shared their published and unpublished work and commented on sections of this chapter.

### Biography

**Reed Pyeritz**, completed his PhD and MD at Harvard and trained in internal medicine at the Peter Bent Brigham Hospital in Boston and medical genetics at the Johns Hopkins Hospital in Baltimore. He is a professor of Medicine and Genetics at the Raymond and Ruth Perelman School of Medicine of the University of Pennsylvania in Philadelphia, where he directs the Center for the Integration of Genetic Healthcare Technologies and serves as vice-chair for academic affairs of the Department of Medicine. He is a senior fellow in both the Center for Bioethics and the Leonard Davis Institute for Health Economics.

His research has focused on several areas, including clinical investigations of heritable disorders of connective tissue and cardiovascular diseases, especially those affecting the thoracic aorta. Currently he is studying how more refined methods of investigating genetic variation, such as cytogenomic arrays and whole genome sequencing, actually increase the level of uncertainty in applying the results clinically.

*Reed E Pyeritz*

Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, USA

### 50.1 DEVELOPMENT OF THE LYMPHATIC SYSTEM

The lymphatic vessels arise from the cardinal vein after the cardiovascular system is established and functional. Lymphatic vessel development commences about embryonic weeks six to seven in humans, when a distinct subpopulation of endothelial cells in the lateral part of the anterior cardinal veins become committed to a lymphatic lineage and sprout laterally to form the vascular sacs. The peripheral lymphatic vasculature is generated by the sprouting of lymphatic vessels from the lymph sacs, followed by merging of the separate lymphatic capillary networks and remodeling and maturation of the lymphatic capillary plexus. LYVE1, a specific lymphatic endothelial marker, is expressed in a subset of endothelial cells in the central veins and is the first indicator of lymphatic commitment. In adults, LYVE1 expression decreases in the collecting lymphatics but remains high in the lymphatic capillaries. PROX1 expression is specific for lymphatic vessels and, in the mouse, Prox1 knockout embryos do not form lymph sacs or lymphatic vessels (1,2). Overexpression of Prox1 in human blood vascular endothelial cells (VECs) downregulates genes specific for VECs and upregulates lymphatic endothelial cell (LEC) gene expression (3,4).

Signals leading to the polarized expression of PROX1 are poorly understood, but Francois and colleagues (5) showed that the expression of homeobox transcription factor SOX18, mutations in which lead to human hypotrichosis-lymphedema-telangiectasia syndrome (OMIM 206823), precedes PROX1 expression and that there are SOX18 binding sites in the promoter of PROX1, indicating that SOX18 acts upstream of

PROX1 in initiating the LEC differentiation program. The protein kinase receptor VEGFR3 is expressed on all endothelial cells early in development but becomes increasingly specific for endothelial cells committed to a lymphatic lineage (3,6). VEGFR3 is activated by VEGF-C and VEGF-D, but during development VEGF-C expression is predominantly in regions where the lymphatic vessels develop (6,7). Mice null for VEGF-C have complete absence of lymphatics, and the heterozygote for the null allele shows severe lymphatic hypoplasia (7). Overexpression of VEGF-C leads to lymphatic hyperplasia in the mouse, although VEGFC mutation has not been reported in humans.

Direct communication between the lymphatic network and the vascular system occurs around 40 days postconception in humans, whereby the lymphatic drainage of the right and left sides of the upper body, which had collected in bilateral jugular lymph sacs, empty into the ipsilateral jugular veins. Failure or delay in completing these communications leads to widespread distortion of lymphatic development termed the jugular lymphatic obstruction sequence (8). The clinical consequences of edema distal to the obstruction will vary depending on whether communication is established and when it occurs. Complete absence of communication is lethal. Distention of the jugular sac produces, among other findings, a cystic hygroma, which causes excess skin growth over the neck, the posterior hairline and hair pattern to be disturbed, and the ears to protrude and rotate. If the jugular sac does not decompress until late in fetal development, the infant will have pterygium coli, or webbing of the neck. Edema of the hands and feet may not be fully resolved at birth, and permanent effects on distal

development will be noted, such as predominance of digital whorls and narrow, hyperconvex nails. If drainage of lymph from the lower quadrants of the fetus is primarily affected, the ileac lymph sacs become distended and excess skin grows over the lower abdomen. Prenatal resolution can result in the prune-belly birth defect.

Defective lymphatic development has consequences for the cardiovascular system (3). Peripheral veins tend to be of large caliber, presumably because of increased venous return from edematous tissues. The frequency of left-sided flow defects (e.g. aortic coarctation, bicuspid aortic valve, hypoplastic left heart) is increased, in part because of the space occupied by the distended jugular sacs.

## 50.2 DISORDERS OF THE LYMPHATIC SYSTEM

Diffuse, acquired blockage of lymphatics, such as by fibrosis, tumor or infection (e.g. *Microfilaria bancrofti*), usually results in edema of the body parts distal to the blockage. However, if the thoracic duct is blocked, anastomosing channels develop between the lymphatic system and systemic veins, and edema does not persist.

A prenatal cystic hygroma is often seen in fetal aneuploidy. If the fetal karyotype is normal, a cystic hygroma detected in the first trimester carries a good prognosis; if it resolves by the mid-second trimester, little distortion of the infant is likely to be noted (70).

Both Turner syndrome (Chapter 50) and Noonan syndrome (Chapter 46) have prominent, multisystem malformations due to fetal lymphatic obstruction. Failure of the jugular lymphatic–venous communication to occur may be the major reason that 98% of embryos with a 45,X karyotype do not survive to term.

The National Lymphedema Network, Inc., maintains a list of various support groups; while many pertain to acquired lymphedema, issues pertinent to various congenital and hereditary conditions can be found ([www.lymphnet.org](http://www.lymphnet.org)).

### 50.2.1 Hereditary Lymphedema I

Hereditary lymphedema 1A (OMIM 153100) is a mainly congenital onset lymphedema, the swelling of the extremities due to failure in the development and/or function of the lymphatics, leading to the accumulation of lymph in the interstitial fluid space. It is highly variable in expression and penetrance, and unaffected obligate heterozygous individuals occur in almost all pedigrees of sufficient size. The age at onset varies from embryonic (as seen on prenatal ultrasound) to middle age. The classic presentation, termed Milroy disease after the physician who gave the first detailed description of the condition in 1892, manifests as congenital edema of the lower half of the body with no other obvious manifestations. The

major features of the disease, variable age at onset and expressivity and reduced penetrance, were described by Milroy (9) over the course of 35 years, in a single family. The complications of Milroy disease include hypoproteinemia due to intestinal loss of albumin, increased susceptibility to infection in the affected limb, and, in some cases, angiosarcoma.

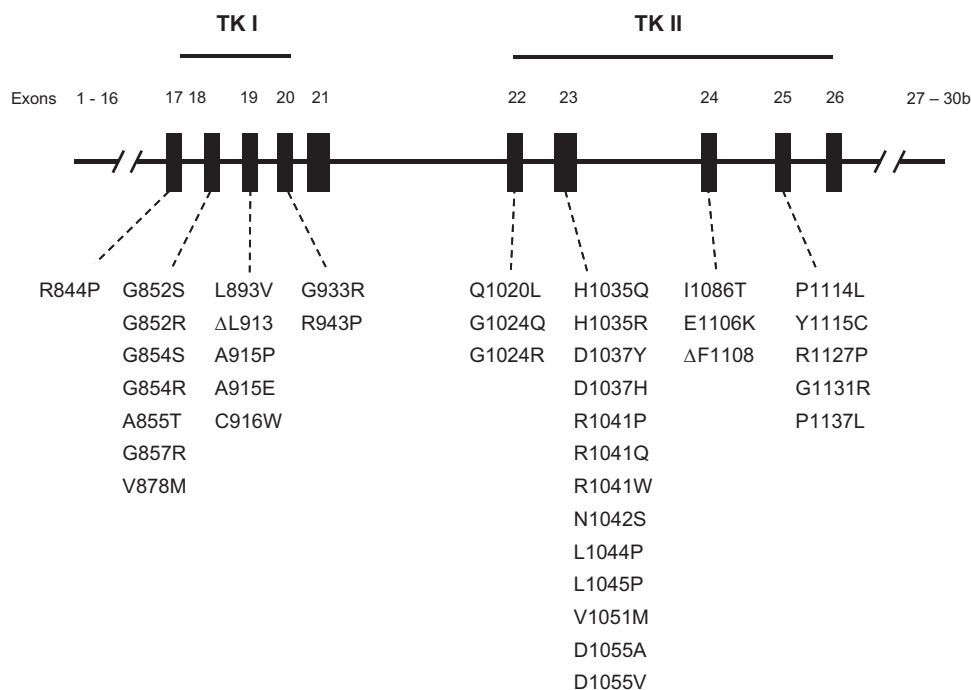

Management is symptomatic. Decongestive therapy consisting of manual lymphatic drainage, wearing of compression garments, skin care and remedial exercise results in improvement of the lymphedema, but is generally temporary. There is no proven medical therapy.

Milroy disease maps to chromosome 5q34-q35 (10–12) and is caused by mutations in the kinase domains of the vascular endothelial growth factor receptor-3 (*VEGF3*, *FLT4*) (13,14). The majority of the mutations are missense mutations occurring in one of the two kinase domains of *VEGFR3*, although a single case of Milroy disease due to a recessively inherited mutation in the ATP binding domain of *VEGFR3* has been reported (15). These mutations are summarized in Figure 50-1. The kinase domain mutations lack the autophosphorylation activity resulting in reduced signal transduction in response to VEGF-C/-D, an obligatory step in lymphoangiogenesis. The autosomal dominant inheritance is apparently due to the accumulation of the nonfunctional receptor on the cell surface, perhaps due to the failure in recycling of the receptor containing one or two copies of the kinase negative receptor subunit.

*VEGFR3* null mice die at around embryonic day E10.5 because of failure in maturation of the perineural vascular plexus into a dendriform hierarchy of large and small vessels (16), although the heterozygote is grossly phenotypically normal. *VEGFR3* is expressed in all endothelial cells during early embryogenesis, but in the course of development its expression in VECs declines, and in the adult, *VEGFR3* expression is largely restricted to the lymphatic endothelium (17). The *chy* mouse, with a *VEGFR3* (I1953F) kinase domain mutation, is characterized by the appearance of chylous fluid in the abdomen, which resolves, and sparse, large cutaneous lymphatic vessels, similar to humans with Milroy disease (18). For a detailed review of lymphangiogenesis see the article by Tammela and Alitalo (19).

Lymphoscintigraphy in Milroy disease shows little or no uptake by peripheral lymphatics of the foot and consequently little or no uptake in the ilioinguinal lymph nodes (20). Generalized in utero edema has been observed in individuals with *VEGFR3* mutations, but this edema resolved spontaneously, either in utero or after birth (21).

Hereditary lymphedema 1B (OMIM 611944) was described by Malik and Grzeschid (22) in a single Pakistani family and assigned to the interval 6q16.2-q22.1 by microsatellite linkage analysis. The lymphedema

**FIGURE 50-1** VEGFR-3 (FLT4) mutations causing hereditary lymphedema.

was congenital, progressive, and confined to the lower limbs. Full expression occurred by puberty and resolved by 40–45 years of age. Autosomal dominant inheritance with reduced penetrance was observed, as in Milroy disease. Region 5q34-35 was ruled out by linkage analysis, and pathological mutations in the candidate gene *FOXO3A* were not found by sequence analysis of the coding region of *FOXO3A*. The region of linkage contains approximately 70 genes, several of which are plausible candidate genes for lymphedema.

Hereditary lymphedema 1C (OMIM 613480) has an early onset of uncomplicated lymphedema of the legs and hands, and is inherited in an autosomal dominant pattern, with variation in age at onset, penetrance and expressivity. Phenotypically it is indistinguishable from Milroy disease, but is caused by missense mutations in *GJC2* coding for connexin 47. These mutations occur in both the extracellular and intracellular domains of connexin 47, and the only common feature of the six mutations that have been described is that they change an amino acid that is highly conserved in mammalian evolution (23). In the two extracellular mutations, expression of the mutant connexin 47 failed to form gap junction plaques when expressed in HeLa cells in culture, and thus failed to communicate electrically with adjacent cells. The four intracellular mutations formed plaques, but their gap junction activity was abnormal. This suggests that these *GJC2* mutations cause lymphedema through failure of intracellular communication. Whether this failure to communicate is between adjacent lymphatic endothelial

cells or endothelial cell and lymphatic smooth muscle cells is unknown. Inactivating mutations in *GJC2* cause Pelizaeus-Merzbacher-like disease (PMLD; OMIM 608804) and connexin 47 is usually considered a central nervous system (CNS) connexin. The relationship between the severe CNS dysmyelination seen in autosomal recessive PMLD and the phenotype of lymphedema seen in dominantly inherited lymphedema in individuals with missense mutations in the same gene is unexplored.

### 50.2.2 Hereditary Lymphedema II

Hereditary lymphedema II (OMIM 153200) is a dominantly inherited, pubertal or adult-onset lymphedema predominantly affecting the legs, but with involvement of the arms, face and larynx in some families. Meige (24) described eight affected individuals in a four-generation family, and the disorder often bears his eponymous designation. Some individuals are first diagnosed with myxedema, and pleural effusion may be present. The nosology of hereditary lymphedema II is unclear, and until the specific gene(s) involved are identified the existence of hereditary lymphedema II as a distinct genetic entity is uncertain.

### 50.2.3 Lymphedema-Distichiasis Syndrome

Lymphedema-distichiasis syndrome (OMIM 153400) is characterized by bilateral lymphedema, usually of the legs, and having a peripubertal age at onset and

distichiasis. These patients often come to medical attention because of corneal abrasions caused by the presence of a double row of eyelashes (distichiasis) (25). The disorder was localized to 16q24.3 by linkage in three families (26), and *FOXC2* was implicated in the study of a patient with a (Y;16) chromosomal translocation (27). Fang et al. (27) went on to identify truncation mutations in two families in the *FOXC2* gene, a member of the forkhead/winged-helix family of transcription factors. This was followed by numerous reports of truncation mutations, leading to haploinsufficiency for *FOXC2* causing lymphedema-distichiasis syndrome (28,29). Mellor and colleagues (30) reported abnormal isotope uptake on lymphoscintigrams, and significant lymphatic backflow, and that all patients with *FOXC2* mutations studied demonstrated backflow on Doppler ultrasound examination, consistent with valve failure.

Studies of the *FOXC2* null mice showed that they died at approximately E12.5, with severe abnormalities of the developing mesenchyme (31). The heterozygous null animals uniformly showed lymphedema due to defective valves and enhanced recruitment of vascular mural cells to cutaneous lymphatic capillaries, and aberrant hair follicles arising from the meibomian gland (32,33), recapitulating the phenotypes observed in humans with lymphedema-distichiasis syndrome. Cederberg and colleagues (34) reported reduced body weight, relatively greater insulin sensitivity, and hypertriglyceridemia in heterozygous null mice compared to normal mice, consistent with the diabetes mellitus reported in members of a family with *FOXC2* mutation.

Multiple cases of lymphedema, occurring in the presence and absence of distichiasis, have occurred in patients with missense substitutions in *FOXC2* (30,35). These missense mutations alter the transactivational activity of *FOXC2*, indicating that the haploinsufficiency in lymphedema-distichiasis could arise by multiple molecular mechanisms (35).

#### 50.2.4 Hennekam Lymphangiectasia-Lymphedema Syndrome

Hennekam lymphangiectasia-lymphedema syndrome (OMIM 235510) is an autosomal recessive syndrome of intestinal lymphangiectasia with severe lymphedema of the face and genitalia and severe mental retardation first reported in a highly inbred Dutch kindred (36). The phenotype was localized by homozygosity mapping to chromosome 18q21, and analysis of the candidate gene *CCBE1* showed that mutations in the calcium-binding EGF domain of this gene caused generalized lymphatic dysplasia in a subset of Hennekam patients (37,38). *CCBE1* was identified as a candidate gene based on the finding that mutation in the same domain of the zebrafish *ccbe1* gene led to the failure of embryonic

lymphangiogenesis and venous sprouting (39). Alders and colleagues (37) found that non-disease causing changes in human *CCBE1* could rescue the zebrafish phenotype, but that the homologous Hennekam mutations could not. *CCBE1* mutations occurred in only a subset of patients as evidence for genetic heterogeneity in Hennekam syndrome (37).

#### 50.2.5 Hypotrichosis-Lymphedema-Telangiectasia Syndrome

Hypotrichosis-lymphedema-telangiectasia syndrome (OMIM 607823) was localized to chromosome 20q13 by homozygosity mapping in two consanguineous families, and the *SOX18* transcription factor was considered a plausible candidate gene for the human disease because of the combination of hair and cardiovascular anomalies in the mouse ragged phenotype (40). Both dominant and recessive inheritance occurred, with the alleles causing dominant inheritance having a mutation occurring in a position homologous to that of the four dominant ragged mutations in the transactivation domain of the mouse. The two recessive mutations occurred in the alpha-helix of the DNA-binding domain of *SOX18*. *SOX18* directly activates *Prox1* transcription by binding to its proximal promoter. *PROX1* is considered a “master regulator” of lymphatic development. The overexpression of *Sox18* in blood VECs induces the expression of *Prox1* and other lymphatic endothelial markers, and the *Prox1* null mouse is characterized by a complete blockage of lymphatic endothelial cell differentiation from the cardinal vein (5). The *Ra<sup>op</sup>* allele of the mouse leads to endothelial hyperplasia in the microvasculature and inadequate recruitment of pericytes to the maturing blood microvessels reminiscent of the pericyte maturation defect noted in the *Foxc2* null heterozygote (41). *Sox7* and *Sox17* are strain-specific modifiers of the lymphoangiogenic defects noted in *Sox18* null mice, suggesting that they may also be involved in the expression of lymphatic defects in humans (42).

#### 50.2.6 Cholestasis-Lymphedema Syndrome (Aagaes Syndrome)

Cholestasis-lymphedema syndrome (LCS; OMIM 124900) was first described in consanguineous families of Norwegian origin. It is characterized by lymphedema and early onset, recurrent cholestasis. Aagaes syndrome was mapped to a 6.6 cM interval of chromosome 15q by Bull et al. (43), and Fruwirth et al. (44) later mapped a second locus for LCS on chromosome 18 by a combination of linkage and haplotype mapping. Phenotypic similarity between the families suggested a second locus, LCS2, for cholestasis-lymphedema syndrome. The causative genes for LCS1 and LCS2 and the insight they would provide

to the pathogenesis of these disorders have eluded investigators.

### 50.2.7 Choanal Atresia and Lymphedema

Choanal atresia and lymphedema (OMIM 613611) was first reported in a consanguineous Yemenite family by Qazi et al. (45), and mapped to the region 1q32-q41 by homozygosity mapping (46). This interval contains the *PTPN14* protein tyrosine phosphatase gene, and reasoning that lymphedema is part of the phenotype of Noonan syndrome (OMIM 176876), which is caused by mutations in the homologous *PTPN11* gene, Au et al. (46) identified a patient homozygous for a frameshift mutation at residue 194, which led to a premature chain termination at residue 211. This mutation interrupted a FREM domain (erzin-radixin-meosin family of cell adhesion molecules) in *PTPN14*. They examined two mouse embryonic stem cell lines in which exon-trapping vectors were integrated within the *Ptpn14* gene. In three chimeric animals generated from the exon-trap located in intron 5, homozygous for the intron-5 trap, they observed lymphedema in a fraction of the offspring, and they confirmed high levels of expression of *PTPN14* in lymphatic endothelial cells, and concluded that this gene was responsible for the phenotype observed in the mouse and in humans.

Mutations in transcription factors *FOXC2*, *SOX18*, *CCBE1* and *NEMO* cause lymphedema-related syndromes OMIM153400, OMIM 607823, OMIM 235510 and OMIM 300248, respectively; mutation in *PTPN11* causes Noonan syndrome associated with lymphedema; and tyrosine kinase *VEGFR3* mutation causes Milroy disease (OMIM 153100), indicating both the genetic heterogeneity of lymphedema and the complexity of lymphoangiogenesis.

## 50.3 MENDELIAN DISORDERS AFFECTING BOTH THE LYMPHATIC AND VENOUS SYSTEM

### 50.3.1 Klippel-Trenaunay Syndrome

Klippel-Trenaunay syndrome (KTS; OMIM 14900) is defined by cutaneous hemangiomata and hypertrophy of bones and soft tissues (47). There is clear overlap with the Parkes Weber syndrome (OMIM 608355), which has hypertrophy due to arteriovenous malformations. Lymphatic abnormalities are restricted to KTS. Very few familial cases of KTS have been described (48). As with Milroy disease, the only effective treatment of lymphedema is physical therapy involving decongestive therapy, the wearing of pressure garments, remedial exercise and particular attention to hygiene in the affected area. Surgical and therapeutic interventions have not proved effective.

**TABLE 50-1 Mendelian Disorders Affecting the Lymphatics**

Disorder	Inheritance	OMIM No	Locus	Gene	Features
Lymphedema, hereditary, 1A, Milroy's	AD	153100	5q34q35	<i>FLT4 (VEGFR3)</i>	Congenital onset
Lymphedema, hereditary, 1B	AD	611944	6q16.2-q02.1		Congenital onset, fully expressive at puberty
Lymphedema, hereditary, 1C	AD	613480	1q41-q42	<i>GJC2</i>	Congenital (leg), variable onset (arm), pubertal to adult
Lymphedema, hereditary, II	AD	153200			Pubertal or adult onset
Lymphedema-distichiasis syndrome	AD	153400	16q24.3	<i>FOXC2</i>	Bilateral dilated lymphatics; double row of eyelashes
Lymphedema, microcephaly-chorioretinopathy syndrome	AD	152950			Microcephaly frequently with normal intelligence; chorioretinopathy
Hennekam lymphangiectasia-lymphedema syndrome	AR	235510	18q21.32	<i>CCBE1</i>	Generalized lymphatic dysplasia; intestinal lymphangiectasia
Hypotrichosis-lymphedema-telangiectasia syndrome	AR/AD	607823	20q13.33	<i>SOX18</i>	Autosomal dominant and autosomal recessive inheritance reported
Cholestasis-lymphedema syndrome	AR	124900	15q		Aagaes syndrome, jaundice and lymphatic hyperplasia
Yellow nail syndrome	AR	153300			With frequent respiratory tract involvement
Choanal atresia and lymphedema	AR	613611	1q32	<i>PTPN14</i>	Listed under OMIM 603155. May be the same disorder
Ectodermal dysplasia, anhidrotic, with immunodeficiency, osteopetrosis and lymphedema	X	300301	Xq28		Possible mutation in NEMO

AD, autosomal dominant; AR, autosomal recessive; X, X-linked.

## 50.4 VARICOSE VEINS

The common disorder, varicose veins, is considered in this chapter rather than in Chapter 56. This term most commonly refers to increased caliber and tortuosity associated with engorgement of the superficial veins of the leg, with the saphenous being the most prominent. Varicosities may be congenital, but develop in middle age in the vast majority of affected people. As much as 10% of the population of developed countries have varicosities of the legs, and perhaps 10% of them have symptomatic venous insufficiency. Anything that increases pressure and flow in the superficial veins, such as proximal obstruction (pregnant uterus, tumor) or thrombosis of the deep veins, can increase the luminal diameter. Little dilatation is necessary before the venous valves become incompetent, which in turn increases pressure upstream and causes further dilatation. Chronic dilatation results in vascular remodeling and persistent valvular failure. The clinical results are discomfort, mild edema, susceptibility to venous rupture with minor trauma, and venous stasis, which increases the susceptibility to thrombosis. About 20% of people with chronic, symptomatic venous varicosities develop skin breakdown (varicose ulcers). Conservative treatment of support stockings and elevation of the legs can provide temporary relief of discomfort but does not address the fundamental problem. Surgical treatment has involved ligation and stripping of larger vessels and sclerosis of smaller ones. In all cases, recurrence rates are high (40%). In 1999, the US Food and Drug Administration approved the use of radiofrequency heat to collapse distended veins. Although this procedure is much less invasive than other surgical approaches and produces little short-term disability, the long-term effectiveness is unclear.

*Varicose veins are the result of an improper selection of grandparents.*

—William Osler, *Aphorism 335*

Many factors predispose to varicose veins and venous insufficiency of the lower extremity, including age (more common the older the subject), gender (increased in females), number of pregnancies, weight (increased in obesity), lifestyle (increased with prolonged standing), and positive family history (49–51). The impact of family history is subject to the typical inadequacies (imperfect sensitivity and specificity) of this method (52,53). Certain heritable disorders of connective tissue, especially Ehlers-Danlos of the classical and vascular types and the Marfan syndrome, predispose to varicose veins. However, the vast majority of venous varicosities are not simply inherited. Multifactorial inheritance was suggested by studies of large families (54). Another study of 134 relatively small families found that when neither parent was affected, the risk that a child had varicosities was 20%. When one parent was affected, the risk to a

son was 25% and to a daughter was 62%. When both parents were affected, the risk to any child was 90%. Having an affected mother may confer greater risk than if the father is the one parent involved (55).

Whether a specific tendency to defective or absent venous valves is inherited remains uncertain (56). Venous capacity and compliance show modest heritability (0.3) when studied in twins (57). Attempts to identify predisposing genes began in the past decade (51).

In part because of the occurrence of venous varicosities in certain heritable disorders of connective tissue, levels of various signaling molecules and production of components of the extracellular matrix have been examined in tissue from patients. For example, transcription of vascular endothelial growth factor (VEGF) and some of its receptors is altered in segments of varicose veins (58). In addition, a variety of genes encoding proteins involved in the extracellular matrix and its remodeling are differentially expressed in smooth muscle cells isolated from varicose veins (59,60). However, abnormalities in the actual tissue are always subject to issues of cause and effect. Examination of cultured cells from varicose veins might surmount that obstacle. Synthesis of type III collagen was reduced in both cultured smooth muscle cells and dermal fibroblasts compared with controls (61,62).

Immunostaining of the intima of varicose veins found increased expression of HIF-1 $\alpha$ , suggesting a role for hypoxia (63). A suggestion of endothelial cell dysfunction in varicose veins (64,65) led Sverdlova and colleagues (66) to examine the prevalence of a thermolabile variant of methylene-tetrahydrofolate reductase (MTHFR), C677T, in patients with lower limb varicose veins. They observed a twofold increase in the risk of varicose veins among individuals homozygous or heterozygous for the thermolabile allele. The C677T variant of MTHFR is both thermolabile and less active than the normal allele and is associated with elevated levels of plasma homocysteine (67). Hyperhomocysteinemia due to polymorphic variation in *MTHFR*, mutations in cystathionine  $\beta$ -synthase, folate, and vitamin B<sub>12</sub> deficiency, and other factors is common and potentially predisposes to varicose veins (68).

Rosbotham and colleagues (69) reported venous abnormalities in affected members of a lymphedema-distichiasis family in which lymphedema-distichiasis was linked to chromosome 16q24 and presumed to carry a mutation in the forked head transcription factor, FOXC2. Brice and colleagues (20) reported that 49% of affected individuals, in a sample of lymphedema-distichiasis families with FOXC2 mutations or linkage to 16q24, had early-onset varicose veins. These results support an important role for FOXC2 in the development of both the venous and lymphatic systems (30). Studies of FOXC2 in patients or families ascertained through the presence of varicose veins without lymphedema-distichiasis are required to

evaluate the role of this gene in the development of varicose veins in the general population.

## 50.5 GENETIC COUNSELING

Genetic diseases that affect the lymphatics are rare and heterogeneous, making them problematic from a counseling perspective. Milroy disease, hereditary lymphedema 1C, lymphedema-distichiasis syndrome and Hennekam syndrome are amenable to molecular diagnosis, but there are no prevalent mutations that can be screened in the general population. In families with known mutations, screening while possible, is complicated by the extreme variation occurrence of any feature (because of lack of penetrance), of age of onset of features, and of severity of the disease in carriers of the mutation. Lymphedema can be detected by prenatal ultrasound, but the specificity of ultrasound for the detection of lymphedema is uncertain and the clinical outcome, in cases where an abnormal ultrasound is present, cannot be reliably predicted.

### Biography

Reed Pyeritz completed his PhD and MD at Harvard and trained in internal medicine at the Peter Bent Brigham Hospital in Boston and medical genetics at the Johns Hopkins Hospital in Baltimore. He is a professor of Medicine and Genetics at the Raymond and Ruth Perelman School of Medicine of the University of Pennsylvania in Philadelphia, where he directs the Center for the Integration of Genetic Healthcare Technologies and serves as vice-chair for academic affairs of the Department of Medicine. He is a senior fellow in both the Center for Bioethics and the Leonard Davis Institute for Health Economics.

His research has focused on several areas, including clinical investigations of heritable disorders of connective tissue and cardiovascular diseases, especially those affecting the thoracic aorta. Currently he is studying how more refined methods of investigating genetic variation, such as cytogenomic arrays and whole genome sequencing, actually increase the level of uncertainty in applying the results clinically.

## The Genetics of Cardiac Electrophysiology in Humans

*Reed E Pyeritz*

Perelman School of Medicine at the University of Pennsylvania,  
Philadelphia, PA, USA

### 51.1 INTRODUCTION

Dysrhythmias typically are thought to occur because of primary or secondary abnormalities in cardiac electrophysiology. These abnormalities can include primary alterations in myocardial conduction and repolarization or those occurring as a result of structural heart disease. A significant portion of the individuals found to have abnormalities of rhythm and conduction are now known to have a genetic basis, with familial inheritance notable. Familial inheritance of dysrhythmias and conduction disorders indicates that genetic factors play an integral role in development of these abnormalities. Understanding the underlying genetic defects responsible for these disorders has indeed provided insights into the mechanisms leading to the clinical picture and promises to impact the therapeutic strategies used in the care of these patients. Over the course of the past 15 years, our understanding of the genetic abnormalities in a variety of cardiomyopathies, long-QT syndrome (LQTS), Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT), and newer disorders has led to general concepts of cardiovascular disease. In this chapter, the clinical features and management of familial dysrhythmias and conduction disorders are discussed and the current understanding of the genetic abnormalities associated with these disorders is reviewed.

### 51.2 SPECIFIC CARDIAC DYSRHYTHMIAS

The entire cardiac electrical system can be affected by genetic abnormalities, leading to atrial and ventricular tachydysrhythmias, sinus node dysfunction, or atrioventricular (AV) block. Primary dysrhythmias and secondary dysrhythmias (i.e. those associated with structural heart disease) are discussed next.

### 51.3 PRIMARY ABNORMALITIES IN CARDIAC RHYTHM: VENTRICULAR TACHYDYSRHYTHMIAS

#### 51.3.1 Long-QT Syndromes

LQTSs are primary disorders of cardiac repolarization (1), in which prolongation of the QT interval corrected for heart rate (QTc) is seen on the surface electrocardiogram (ECG) along with abnormalities of T wave morphology and sinus bradycardia (Figure 51-1). Syncope, seizures, and sudden death are the clinical features that are commonly seen, occurring because of ventricular tachycardia (VT), especially polymorphic VT or torsade de pointes (Figure 51-2), which can degenerate into ventricular fibrillation (VF). Torsade de pointes, meaning “turning of the points,” is common in all forms of LQTS and describes the varying axis of the QRS complex during VT (1). This dysrhythmia is a subset of polymorphic VT, to be distinguished from monomorphic VT, which has a different morphology and mechanism of development (2,3). Monomorphic VT usually results from reentrant mechanisms and typically can be induced by programmed electrical stimulation. On the other hand, polymorphic VT cannot be induced using programmed electrical stimulation, suggesting that the mechanism is unlikely to be primary reentry. Torsade de pointes, in fact, is thought to be initiated by abnormal automaticity and then maintained by reentrant mechanisms (4). Development of early afterdepolarizations (EADs) appears to be an important mechanism whereby drug-induced action potential prolongation initiates torsade (5,6). Under normal conditions, the ventricle is activated from subendocardium to epicardium by impulses arising in the subendocardial Purkinje network. Mapping data in animal models support the idea that the initial beat in torsade arises in the subendocardium, consistent with a triggered beat arising from an EAD in the Purkinje

**FIGURE 51-1** Electrocardiogram of a 14-year-old female with long-QT syndrome. Note the sinus bradycardia (48 beats/min) and very prolonged QTc of 600ms, with low-amplitude, bifid T waves.

**FIGURE 51-2** Torsade de pointes polymorphic ventricular tachycardia.

system (7). The conditions that evoke EADs markedly prolong repolarization in the mid-myocardium (M-cell region) as well, resulting in a situation in which propagation of EAD-related triggered beats from the subendocardium may be blocked in regions where M-cell action potentials have become especially long, setting up intramural reentrant excitation with a circuit that varies from

beat to beat (8). This perhaps accounts for the distinctive morphology of torsade de pointes (2,9).

Recently, the concept has emerged that defects in currents important for repolarization prolong the action potential but are not directly arrhythmogenic. Rather, action potential duration creates a milieu in which genetically normal, drug-unmodified ion channels or other

electrogenic phenomena further prolong repolarization and precipitate arrhythmias.

The LQTSs have been classified into acquired and genetically inherited forms. Acquired long-QT syndrome (aLQTS) is the most common form of LQTS, with drug-induced LQTS particularly common. Drugs implicated in aLQTS include antiarrhythmic agents such as quinidine or sotalol, tricyclic antidepressants, antibiotics (especially macrolide antibiotics such as erythromycin), antihistamines such as terfenidate, and inhalational anesthetics. aLQTS has also been seen in association with metabolic derangements, including hypokalemia, hypomagnesemia, and hypercalcemia. Additionally, aLQTS has been identified in patients with other cardiac diseases such as cardiomyopathies and myocardial ischemia, as well as under circumstances of intracranial disease (i.e. intracranial surgery, subarachnoid hemorrhage, and increased intracranial pressure).

Four forms of inherited LQTS are known. Romano-Ward syndrome (10,11) and Jervell and Lange-Nielsen syndrome (JLNS; (12)) are the classically described forms of LQTS. More recently, two other disorders, Andersen syndrome (13) and Timothy syndrome (14,15), have been described and studied and the underlying causes were determined. Another disorder, sudden infant death syndrome (SIDS), has also been showed to be LQTS-like in some babies (16).

Romano-Ward syndrome is characterized by autosomal-dominant inheritance with reduced penetrance and is the most common inherited form of LQTS, estimated to have an incidence of one in 10,000 live births worldwide (17–19). JLNS is a seemingly rare condition, with an estimated incidence of one in 1.6 million live births (17–19). This disorder, which is defined as LQTS associated with sensorineural deafness, has been described as having autosomal recessive inheritance since its initial description in 1957 (12). In the past decade, molecular genetic studies have clarified its inheritance, suggesting it to be autosomal-dominant LQTS associated with autosomal-recessive deafness. Finally, SIDS has been shown to be another presentation of inherited LQTS (16). Supportive data were provided by the identification of mutations in the cardiac sodium-channel gene, *SCN5A*, by Ackerman et al. (20), followed by identification of *HERG/KCNH2* mutations in other infants with SIDS (21).

**51.3.1.1 Clinical Features of LQTS.** LQTS is typically identified in individuals presenting with syncope, seizures, or sudden cardiac death that results from episodic ventricular tachydysrhythmias, particularly torsade de pointes and VF (1,17–19,22). Cardiac dysrhythmias have been reported in up to 24% of cases, but the risk of sudden death has been estimated to be <1% per year. These estimates are almost certainly inaccurate, however, as a significant percentage of the 300,000–400,000 sudden deaths occurring in the United States yearly (23) are likely to be the result of this disorder (which goes

unrecognized), and many living patients are asymptomatic and can have normal QT intervals on screening ECGs because of reduced penetrance. Today, many asymptomatic family members are being identified via both screening ECGs and molecular genetic family screening, and therefore, better estimates are likely in the future.

As LQTS may be difficult to diagnose, a set of criteria have been developed by Schwartz et al. (1,1a,22,24). These criteria use a point system in the diagnostic scheme, relying heavily on classical features (Table 51-1). This approach is thought to improve diagnostic accuracy by including major criteria (prolonged QTc > 440ms, stress-induced syncope, family history of LQTS) and minor criteria (congenital deafness, T wave alternans, relative bradycardia, abnormal ventricular repolarization) (Figure 51-3).

The clinical features of LQTS, which occur because of dysrhythmias, are typically associated with triggering events. The most well-described triggers include exercise, anxiety or excitement, auditory events (i.e. telephone or alarm clock ringing), swimming or diving into a pool, and postpartum status. Some patients have events or die during sleep, which is thought to be associated with bradycardia.

In most cases of LQTS, no other abnormalities occur. However, sensorineural deafness is associated with the JLNS form of LQTS, distinguishing it from Romano-Ward syndrome. LQTS has been reported to occur in approximately 1% of children with congenital deafness, and this has led to the recommendation for screening ECGs in this group of children. A recent study from Thailand demonstrated a possible prevalence of 0.7% of JLNS in children with sensorineural deafness at a school for the deaf (25). These children also appear to have more severe ECG abnormalities than Romano-Ward syndrome patients and have a worse prognosis. Other associated abnormalities have been reported rarely in more complex patients with LQTS. Marks et al. (14) described LQTS patients with syndactyly; in this patient subset, LQTS appears to be quite severe, with a high percentage of patients dying in infancy. In most of these patients, the initial presentation included 2:1 AV block due to marked QT prolongation. These patients were initially found in sporadic cases, with both genders being represented, but more recently, families have been identified, and a new syndrome termed Timothy syndrome (15) has been described (Section 51.3.1.4.3). Other patients with LQTS have been described with associated diabetes mellitus or asthma (26,27), as well as those with potassium-sensitive periodic paralysis, dysmorphic features, and skeletal abnormalities, termed Andersen syndrome (13).

**51.3.1.2 Genetics of LQTS.** As previously noted, four forms of inherited LQTS have been described, including autosomal dominant (Romano-Ward syndrome), autosomal recessive (JLNS), and other complex forms (Andersen syndrome and Timothy syndrome), in addition to sporadic cases. Over the past 15 years, the genetic

TABLE 51-1 Diagnostic Criteria in LQTS

Clinical Finding	Points <sup>a</sup>
Electrocardiographic findings <sup>b</sup>	
QT <sub>c</sub> <sup>c</sup>	
>480 ms <sup>1/2</sup>	3

Congenital deafness	0.5
Family history <sup>f</sup>	
Family members with definite LQTS <sup>g</sup>	1
Unexplained sudden cardiac death below	0.5 age 30 among immediate family members

<sup>a</sup>Scoring: <1 point = low probability of LQTS, 2–3 points = intermediate probability of LQTS, >4 points = high probability of LQTS.

<sup>b</sup>In the absence of medications or disorders known to affect these ECG features.

<sup>c</sup>QT<sub>c</sub> calculated by Bazett's formula, where QT<sub>c</sub> = QT.

<sup>d</sup>Mutually exclusive.

<sup>e</sup>Resting heart rate below the second percentile for age.

<sup>f</sup>The same family member cannot be counted twice.

<sup>g</sup>Definite LQTS is defined by an LQTS score >4.

FIGURE 51-3 T wave alternans in a child with long-QT syndrome.

aspects of all four forms of LQTS have been unraveled. In the case of the most common inherited form, Romano-Ward syndrome, the key genes have been identified for all of the mapped subtypes. In 1991, Keating et al. identified genetic linkage to the short arm of chromosome 11 (11p15.5) in several families with Romano-Ward

syndrome (28,29). Shortly thereafter, we demonstrated genetic heterogeneity, several laboratories confirmed this subsequently (30–33). In a collaborative effort (34), linkage was shown for several families to two new loci, the long arm of chromosome 7 (7q35–36) and the short arm of chromosome 3 (3p21). The three loci were later termed

LQT1 (11p15.5), LQT2 (7q35–56), and LQT3 (3p21). A fourth locus (LQT4) on chromosome 4q (4q25–27) was later described as well (35). Most recently, two other genes, both located on chromosome 21q22 (loci LQT5 and LQT6), were identified (36–38) (Figure 51-4). Penetrance in Romano–Ward syndrome is reduced and, in some families, Romano–Ward syndrome appears to occur in a recessively inherited pattern (39).

### 51.3.1.3 Gene Identification in Romano–Ward Syndrome.

**51.3.1.3.1 KVLQT1 or KCNQ1: The LQT1 Gene.** The first of the genes mapped for LQTS, termed LQT1, required 5 years from the time that mapping to chromosome 11p15.5 was first reported to gene cloning (Table 51-2). This gene, originally named *KVLQT1* but more recently called *KCNQ1*, is a novel potassium-channel gene that consists of 16 exons, spans approximately 400 kb, and is widely expressed in human tissues including heart, inner ear, kidney, lung, placenta, and pancreas, but not in skeletal muscle, liver, or brain. In the original report, 11 different mutations (deletion and missense mutations) were identified in 16 LQTS families, establishing *KVLQT1* as LQT1. To date, more than 100 families with *KVLQT1* mutations have been described. Although most of the mutations are “private” (i.e. only seen in one family), there is at least one frequently mutated region (called a “hot spot”) of *KVLQT1* (40,41).

Analysis of the predicted amino acid sequence of KVLQT1 suggests that it encodes a potassium-channel  $\alpha$  subunit (37,38,42) with a conserved potassium-selective pore-signature sequence flanked by six membrane-spanning segments similar to shaker-type channels (Figure 51-4). A putative voltage sensor is found in the fourth membrane-spanning domains (S4) and the selective pore loop is between the fifth and sixth membrane-spanning domains (S5 and S6). Biophysical characterization of the KVLQT1 protein confirmed that KVLQT1 is a voltage-gated potassium-channel protein subunit that requires coassembly (37,38) with a  $\beta$  subunit called minK to function properly (Figure 51-4). Expression of either KVLQT1 or minK alone results in inefficient (or no) current development. When minK and KVLQT1 are coexpressed in either mammalian cell lines or *Xenopus* oocytes, however, the slowly activating delayed-rectifier potassium current ( $I_{Ks}$ ) is developed in cardiac myocytes. Combination of normal and mutant KVLQT1 subunits forms abnormal  $I_{Ks}$  channels and these mutations are believed to act through a dominant-negative mechanism (the mutant form of KVLQT1 interferes with the function of the normal wild-type form through a “poison pill”-type mechanism) or a loss-of-function mechanism (only the mutant form loses activity) (43–45).

Because KVLQT1 and minK form a unit, mutations in minK were also expected to cause LQTS (38), and this fact was subsequently demonstrated (Section 51.3.1.3.5).

**FIGURE 51-4** Chromosomal loci and genes responsible for long QT syndrome.

**TABLE 51-2 Familial Primary Dysrhythmias**

Disease	Rhythm Abnormality	Inheritance	Chromosome Location	Gene
Ventricular arrhythmias				
Romano–Ward syndrome	TdP, VT, VF	AD	3p21, 4q25, 7q35, 11p15.5, 21q22 <sup>b</sup> (3p21); ANK $\beta$ (4q25)	KVLQT1/KCNQ1 (11p15.5); HERG/KCNH2 (7q35); SCN5A minK/KCNE1 (21q22); MiRP1/KCNE2(21q2)
Jervell and Lange-Nielsen syndrome	TdP, VT, VF	AD/AR <sup>a</sup>	11p15.5, 21q22	KVLQT1 (11p15.5); minK (21q22)
Andersen syndrome	TdP, VT, VF, AF	AD	17q23	Kir2.1 (KCNJ2)
Timothy syndrome	VT, VF	AD	12p13.3	Ca(V) 1.2
Brugada syndrome	VT, VF	AD	3p21	SCN5A
Sudden unexpected death syndrome	VT/VF	AD	3p21	SCN5A
Short QT syndrome	TdP, VT, VF	AD	7q35, 11p15.5, 17q23	KCNQ1, KCNH2, KCNJ2
Familial VT	VT	AD	?	?
Familial bidirectional VT	VT	AD	1q42	RyR2
Catecholaminergic polymorphic VT	VT	AD	1q42b	RyR2, CASQ2
Supraventricular arrhythmias				
Familial atrial fibrillation	AF	AD	6q14–16, 10q22, 11p15.5, 21q22 (21q22)	KvLQT1/KCNQ1 (11p15.5); KCNE KCNE2(21q22)
Familial total atrial standstill	SND, AF	AD	?	?
Familial absence of sinus rhythm	SND, AF	AD	?	?
Wolff–Parkinson–White syndrome	AVRT, AF, VF	AD	7q3	AMP-kinase/PRKAG2
Familial PJRT	AVRT	AD	?	?
Conduction abnormalities				
Familial AV block	AVB, AF, SND, VT, SD	AD	19q13	?
Lev-Lengre syndrome	AVB, AF, SND, VT, SD	AD	3p21	SCN5A
Isolated conduction disease	AVB/SND	AD	3p21	SCN5A
Sick sinus syndrome	AVB, SND, VT	AR	3p21	SCN5A
Familial bundle-branch block	RBBB	?	?	?

AD, autosomal dominant; AF, atrial fibrillation; AR, autosomal recessive; AVB, atrioventricular block; AVRT, atrioventricular reciprocating tachycardia; PJRT, permanent form of junctional reciprocating tachycardia; RBBB, right bundle-branch block; SD, sudden death; SND, sinus node dysfunction; TdP, torsade de pointes; VF, ventricular fibrillation; VT, ventricular tachycardia.

<sup>a</sup>Jervell and Lange-Nielsen syndrome: autosomal dominant rhythm abnormality and autosomal recessive sensorineural deafness.

<sup>b</sup>At least one other unknown.

The vast majority of mutations in *KVLQT1* and *minK* are heterozygous mutations in Romano–Ward syndrome patients (38,46,47). *KVLQT1* appears to be the most commonly mutated gene in LQTS.

**51.3.1.3.2 HERG or KCNH2: The LQT2 Gene.** After the initial localization of LQT2 to chromosome 7q35–36 by Jiang et al. (34) (Table 51-2), candidate genes (i.e. genes encoding proteins that could cause repolarization abnormalities if mutated, such as ion channels, modulators of ion channels, members of the sympathetic nervous system) in this chromosomal region were analyzed. Human ether-a-go-go-related gene (*HERG*)—a cardiac potassium-channel gene originally cloned from a brain complementary DNA library (48) and that is expressed in neural crest-derived neurons (49), microglia (50), a wide variety of tumor cell lines (51), and the heart (52)—was found to be mutated in patients with clinical evidence of LQTS (52). Six LQTS-associated mutations were initially identified in *HERG*, including missense mutations, intragenic deletions, and a splicing mutation. Later, Schulze-Bahr et al. (53) confirmed *HERG*, which

is now known as *KCNH2*, as the *LQT2* gene, identifying mutations in other families. Currently, this gene is thought to be the second most common gene mutated in LQTS (second to *KVLQT1*). As with *KVLQT1*, “private” mutations that are scattered throughout the entire gene without preferential clustering are seen.

The *KCNH2* gene consists of 16 exons and spans 55kb of genomic sequence (52). The predicted topology of *HERG* is shown in Figure 51-4 and is similar to *KVLQT1*. Unlike *KVLQT1*, *HERG* has extensive intracellular amino and carboxyl termini, with a region in the carboxyl-terminal domain having sequence similarity to nucleotide-binding domains.

Electrophysiologic and biophysical characterization of *HERG* expressed in *Xenopus* oocytes established that *HERG* encodes the rapidly activating delayed-rectifier potassium current ( $I_{Kr}$ ; (54,55)), and electrophysiologic studies of LQTS-associated mutations demonstrated a loss-of-function or a dominant-negative (56) mechanism of action. In addition, protein trafficking abnormalities have been shown to occur (57,58). This channel has been

shown to coassemble with  $\beta$  subunits for normal function, similar to that seen in  $I_{Ks}$ . McDonald et al. (59) initially suggested that the complexing of *HERG* with *minK* is needed to regulate the  $I_{Kr}$  potassium current. Bianchi et al. (60) provided confirmatory evidence that *minK* is involved in regulation of both  $I_{Ks}$  and  $I_{Kr}$ . Most recently, Abbott et al. (36) identified MiRP1 as a  $\beta$  subunit for *HERG* (Section 51.3.1.3.6).

Recently, Zhang et al. (61) identified an intronic variant in *KCNH2* (T1945+6C) in which splicing assay analysis showing downstream intron retention and complementary DNA with the retained intron 7 failing to produce functional channels, consistent with potential disease-causing dysfunction. This finding potentially expands the disease-causing mechanisms in LQTS.

**51.3.1.3.3 SCN5A: The LQT3 Gene.** Utilization of the candidate gene approach established that the gene responsible for chromosome 3-linked LQTS (LQT3) (62) is the cardiac sodium-channel gene *SCN5A* (63,64) (Table 51-2). *SCN5A* is highly expressed in human myocardium and brain, but not in skeletal muscle, liver, or uterus (64,65). It consists of 28 exons that span 80kb and encodes a protein of 2016 amino acids with a putative structure that consists of four homologous domains (DI–DIV), each of which contains six membrane-spanning segments (S1–S6) similar to the structure of the potassium-channel  $\alpha$  subunits (Figure 51-4) (66). Mutation analysis identified three mutations—one 9 bp intragenic deletion ( $\Delta K_{1505}P_{1506}Q_{1507}$ ) and two missense mutations ( $R_{1644}H$  and  $N_{1525}S$ )—in six LQTS families (63,64); when expressed in *Xenopus* oocytes, all mutations generated a late phase of inactivation-resistant, mexiletine- and tetrodotoxin-sensitive whole-cell current via different mechanisms (67,68). Two of the three mutations showed dispersed reopening after the initial transient, but the other mutation showed both dispersed reopening and long-lasting bursts. These results suggested that *SCN5A* mutations act through a gain-of-function mechanism (the mutant channel functions normally, but with altered properties such as delayed inactivation) and that the mechanism of chromosome 3-linked LQTS is persistent nonactivated sodium current in the plateau phase of the action potential. An et al. (69) also showed that not all mutations in *SCN5A* are associated with persistent current and demonstrated that *SCN5A* interacted with  $\beta$  subunits. Furthermore, mutations in *SCN5A* have been shown to result in widely different clinical phenotypes and different responses to medications (70). Novel mutations in *SCN5A* were identified by our laboratory in patients with Brugada syndrome and idiopathic VF (71), disorders with normal QT interval but ST segment elevation in the right precordial leads (Table 51-2). Electrophysiologically, these mutations result in more rapid recovery from inactivation of the mutant channels or loss of function causing the Brugada syndrome-type phenotype (Section 51.3.2). In addition, mutations in this gene cause conduction system disease (72) and SIDS (1,20,22),

sudden unexplained nocturnal death syndrome (see later section), and, in cases with recessive inheritance and homozygous mutations, sick sinus syndrome (73) (Table 51-2).

**51.3.1.3.4 Ankyrinb or AnkK: The LQT4 Gene.** Initially mapped in 1995 to chromosome 4q25–25 by Schott et al. (35) in a large French family with autosomal-dominant LQTS associated with sinus bradycardia due to sinus node dysfunction and atrial fibrillation (AF), the gene remained elusive until 2003. Mohler et al. (74) identified ankyrinb or ankyrin2 (*AnkK*) as the disease-causing gene. This gene encodes a protein with three major isoforms with molecular weights of 440, 220, and 150kDa generated by alternative splicing. The major isoform in the heart is the 220kDa form. Ankyrins are adapter proteins that link integral membrane proteins to the spectrin-based cytoskeleton (75) and contain three functional domains that consist of the membrane-binding domain, the spectrin-binding domain, and the regulatory domain. These proteins bind to several ion-channel proteins, including the voltage-sensitive sodium channel ( $I_{Na}$ ), anion exchanger ( $Cl^-/HCO_3^-$  exchanger), sodium–potassium ATPase, sodium–calcium exchanger (NCX or  $I_{Na-Ca}$ ), and calcium-release channels, including those mediated by the ryanodine receptor (RyR2) and the inositol triphosphate receptor. Mutations in *ANKK* appear to act by a loss-of-function mechanism. It is likely that mutations in this gene cause a clinical phenotype by disrupting the cytoskeletal framework, which results in compromise of channel function or of the trafficking of channels to their proper locale. A murine model of mutant *ANKK* results in clinical features similar to those seen in humans, and findings indicative of calcium-handling abnormalities (74) and sodium-channel dysfunction (76) have been reported.

**51.3.1.3.5 minK or KCNE1: The LQT5 Gene.** The *minK* (*IsK* or *KCNE1*) gene was initially localized to chromosome 21 (21q22.1) and found to consist of three exons that span approximately 40 kb (77). It encodes a short protein consisting of 130 amino acids and has only one transmembrane-spanning segment with small extracellular and intercellular regions (Figure 51-4). When expressed in *Xenopus* oocytes, it produces potassium current that closely resembles  $I_{Ks}$  in cardiac cells (37,38). The fact that the *minK* clone was expressed only in *Xenopus* oocytes and not in mammalian cell lines raised the question whether *minK* is a human-channel protein. With the cloning of *KVLQT1* and coexpression of *KVLQT1* and *minK* in both mammalian cell lines and *Xenopus* oocytes, it became clear that *KVLQT1* interacts with *minK* to form the cardiac  $I_{Ks}$  (37,38); *minK* alone cannot form a functional channel but induces  $I_{Ks}$  by interacting with endogenous *KVLQT1* protein in *Xenopus* oocytes and mammalian cells. Bianchi et al. (60) also showed that mutant *minK* results in abnormalities of  $I_{Ks}$  and  $I_{Kr}$  and in protein-trafficking abnormalities. McDonald et al. (59) showed that *minK* also interacts with *HERG*,

regulating  $I_{K_r}$ . Splawski et al. (78) demonstrated that *minK* mutations cause LQT5 when they identified mutations in two families with LQTS (Table 51-2). In both cases, missense mutations (S74I; D76N) were identified that reduced  $I_{K_s}$  by shifting the voltage dependence of activation and accelerating channel deactivation. This was later confirmed by others (46,47) and further supported by the fact that a mouse model with mutant *minK* (79) developed a phenotype (which included deafness). The functional consequences of these mutations include delayed cardiac repolarization and, hence, an increased risk of dysrhythmias (46,47,80).

**51.3.1.3.6 MiRP1 or KCNE2: The LQT6 Gene.** The *MiRP1* (minK-related peptide 1 or *KCNE2*) gene is a novel potassium-channel gene cloned and characterized by Abbott et al. (36). This small integral membrane subunit protein assembles with *HERG* (LQT2) to alter its function and enable full development of  $I_{K_r}$  (Figure 51-4). *MiRP1* is a 123-amino-acid-channel protein with a single predicted transmembrane segment similar to that described for *minK*. Chromosomal localization studies mapped this *KCNE2* gene to chromosome 21q22.1, within 79kb of *KCNE1* (*minK*) and arrayed in opposite orientation. The open reading frames of these two genes share 34% identity, and both are contained in a single exon, suggesting that they are related through gene duplication and divergent evolution.

Three missense mutations associated with dysrhythmias were identified in *KCNE2* by Abbott et al. (36), and biophysical analysis demonstrated that these mutants form channels that open slowly and close rapidly, thus diminishing potassium currents. In one case, the missense mutation, a C-to-G transversion at nucleotide 25 that produced a glutamine (Q)-to-glutamic acid (E) substitution at codon 9 (Q9E) in the putative extracellular domain of *MiRP1*, led to the development of torsade de pointes and VF after intravenous clarithromycin infusion (i.e. drug induced). Therefore, similar to *minK*, this channel protein acts as a  $\beta$  subunit but, by itself, leads to risk of ventricular arrhythmia when mutated (Table 51-2). These similar channel proteins (i.e. *minK* and *MiRP1*) suggest that a family of channels exist that regulate ion-channel  $\alpha$  subunits. The specific role of this subunit and its stoichiometry remain unclear and are currently hotly debated.

#### 51.3.1.4 Complex Forms of LQTS.

##### 51.3.1.4.1 Jervell and Lange-Nielsen Syndrome.

**51.3.1.4.1.1 Clinical Features.** As noted previously, patients with JLNS have severe QT interval prolongation; episodic tachydysrhythmias, including torsade de pointes, syncope, and/or sudden death; and sensorineural deafness (1,12). The deafness is autosomal recessive, whereas the LQTS is autosomal dominant but severe (19).

**51.3.1.4.1.2 Genetics.** Neyroud et al. (81) reported the first molecular abnormality in patients with JLNS when they reported on two families in which three children were affected by JLNS, finding a novel homozygous

deletion–insertion mutation of *KVLQT1* (Table 51-2). A deletion of 7bp and an insertion of 8bp at the same location led to premature termination at the C-terminal end of the *KVLQT1* channel. At the same time, Splawski et al. (15a) identified a homozygous insertion of a single nucleotide that caused a frameshift in the coding sequence after the second putative transmembrane domain (S2) of *KVLQT1*. Together, these data strongly suggested that at least one form of JLNS is caused by homozygous mutations in *KVLQT1*. This has been confirmed by others (40,45,82–84).

As a general rule, heterozygous mutations in *KVLQT1* cause Romano–Ward syndrome (LQTS only), whereas homozygous (or compound heterozygous) mutations in *KVLQT1* cause JLNS (LQTS and deafness). The hypothetical explanation suggests that although heterozygous *KVLQT1* mutations act by a dominant-negative mechanism (85), some functional *KVLQT1* potassium channels still exist in the stria vascularis of the inner ear. Therefore, congenital deafness is averted in patients with heterozygous *KVLQT1* mutations. For patients with homozygous *KVLQT1* mutations, no functional *KVLQT1* potassium channels can be formed. It has been shown by in situ hybridization that *KVLQT1* is expressed in the inner ear (81), suggesting that homozygous *KVLQT1* mutations can cause the dysfunction of potassium secretion in the inner ear and lead to deafness (79). However, it should be noted that incomplete penetrance exists and not all heterozygous or homozygous mutations follow this rule (86).

As with Romano–Ward syndrome, if *KVLQT1* mutations can cause the phenotype, it could be expected that *minK* mutations could also be causative of the phenotype (JLNS). Schulze-Bahr et al. (83), in fact, showed that mutations in *minK* result in JLNS syndrome as well (Table 51-2), and this was confirmed subsequently (47,84). Hence, abnormal  $I_{K_s}$ , whether it occurs because of homozygous or compound heterozygous mutations in *KVLQT1* or *minK*, results in LQTS and deafness.

##### 51.3.1.4.2 Andersen Syndrome (LQT7).

**51.3.1.4.2.1 Clinical Aspects.** Andersen et al. (13) identified a complex phenotype including ventricular arrhythmias, potassium-sensitive periodic paralysis, and dysmorphic features. The dysmorphisms included hypertelorism, broad nasal root, defects of the soft and hard palate, and short stature. More recently, skeletal abnormalities have broadened the phenotype (87). These skeletal features include micrognathia, clinodactyly, syndactyly, and scoliosis. The associated cardiac abnormalities include QTc prolongation, VT, VF, and atrial arrhythmias. Torsades de pointes and bidirectional VT have been seen. In addition, repolarization abnormalities affecting late repolarization and resembling giant U waves are common. Sudden death has not been reported as a major risk in this disorder. Andelfinger et al. (87) also reported sex-specific variable expression, as well as other clinical features

including unilateral dysplastic kidney and congenital heart disease (bicuspid aortic valve, coarctation of the aorta, valvular pulmonic stenosis).

**51.3.1.4.2.2 Genetics: Kir2.1 or KCNJ2: The LQT7 Gene.** Andersen syndrome was originally mapped to chromosome 17q23–q24.2 by Plaster et al. (88) using genome-wide linkage analysis. The critical region within this locus was narrowed and candidate gene mutation screening identified mutations in *KCNJ2*, which encodes an inward-rectifier potassium channel called Kir2.1 ( $I_{K1}$ ; 588). This channel is highly expressed in the heart and plays a role in phase 4 repolarization and in the resting membrane potential. Multiple gene mutations have been identified to date, with relatively high penetrance noted. Functional studies have demonstrated reduction or suppression of  $I_{K1}$  by a haploinsufficiency or dominant-negative effect (89,90). Lange et al. (89) generated known *KCNJ2* mutants that did not yield any measurable potassium currents in CHO cells, consistent with failure to form functional homomultimeric complexes and non-functional channels. In addition, Bendahhou et al. (91) demonstrated that defective Kir2.1 channels may not traffic to the membrane properly. This gene may play a role in developmental signaling pathways as well, which is believed to be the cause of the dysmorphisms (87).

Analysis of a variety of *KCNJ2* mutations demonstrated that many of these mutations included residues implicated in binding membrane-associated phosphatidylinositol 4,5-bisphosphate (92). It should be noted that nearly 40% of cases do not segregate with this gene, suggesting that genetic heterogeneity exists (93).

#### **51.3.1.4.3 Timothy Syndrome.**

**51.3.1.4.3.1 Clinical Aspects.** This complex disorder is characterized by multisystem dysfunction, including webbing of fingers and toes (syndactyly), immune deficiency, intermittent hypoglycemia, a cognitive immune deficiency, cognitive abnormalities, autism, dysmorphic features, various forms of congenital heart disease, and lethal arrhythmias associated with LQTS (14,15a).

**51.3.1.4.3.2 Genetics.** This autosomal-dominant disorder was described initially by Marks et al. (14), and more recently, the genetic basis of this syndrome was described by Splawski et al. (15a). Mutations in *Ca(V)1.2*, the L-type calcium channel, which is expressed in all affected tissues, was shown to produce maintained inward  $Ca^{2+}$  overload in multiple cell types and, in the heart, causes prolonged  $Ca^{2+}$  current, delaying cardiomyocyte repolarization and increasing arrhythmia risk.

**51.3.1.5 Genotype–Phenotype Correlations in LQTS.** Moss et al. (94) showed that the ECG manifestations of LQTS were in great part determined by the channel mutated. Different T wave patterns were clearly evident when comparing tracings from patients with mutations in LQT1, LQT2, and LQT3. More recently, Zareba et al. (95) showed that the mutated gene may result in a specific clinical phenotype with different triggers and may predict outcome. For instance, these

authors suggested that mutations in LQT1 and LQT2 resulted in early symptoms (i.e. syncope), but the risk of sudden death was relatively low for any event. In contrast, mutations in LQT3 resulted in a paucity of symptoms but, when symptoms occurred, they were associated with a high likelihood of sudden death. Zareba et al. (96) showed that the location of mutations in *KCNQ1* plays no role in clinical course. However, Shimizu et al. (97) showed mutation site-specific differences in arrhythmic risk and sensitivity to sympathetic stimulation in LQT1 patients, with those having transmembrane mutations having a greater risk of early-onset cardiac events and greater sensitivity to sympathetic stimulation compared with patients having C-terminal mutations. Moss et al. showed that pore mutations in LQT2 have higher risk, and effects of age and gender based on genotype were also reported (98). In the latter case, Zareba et al. showed that, during childhood, the risk of cardiac events was significantly higher in LQT1 and LQT3 males than females, with no gender-related differences in the risk of cardiac events among LQT2 and LQT3 carriers. In adulthood, LQT2 females and LQT1 females had a significantly higher risk of cardiac events than respective males. The lethality of cardiac events was higher in LQT3 males and females, and higher in LQT1 and LQT2 males than females. Compound mutation, which reportedly occurs in approximately 8% of subjects, appears to cause longer QTc intervals, worse and more frequent cardiac events, and, in general, a more severe phenotype than other mutations, and worse disease than expected (99).

Neonates appear to have gene-specific clinical features as well. Lupoglazoff et al. (100) studied 23 neonate probands and demonstrated that 2:1 AV block is common and usually associated with LQT2 mutations, with a poor prognosis during the first month of life. In contrast, LQT1 mutations in this patient subgroup appeared to be correlated with sinus bradycardia and good short-term prognosis with  $\beta$ -blocker therapy. Ackerman et al. (20) and Moss et al. (101) showed that swimming is a common trigger for symptoms in LQT1 patients, whereas Wilde et al. (102) have found auditory triggers to be common in LQT2. LQT3, on the other hand, appears to be associated with sleep-associated symptoms. More recently, Choi et al. (103) evaluated 388 subjects with LQTS for LQT gene mutations and identified 43 individuals with swimming-related events (11%). Among this group, 65% had mutations in LQT1, with 21% having RyR2 mutations and 5% LQT2 mutations. Coupled with the findings by Moss et al. (101), it could be suggested that understanding the underlying cause of LQTS in any individual could be used to improve survival by prevention and gene-specific therapy.

**51.3.1.6 Management of LQTS.** At present, there are four classical modalities for treatment of LQTS that have withstood the test of time: (i)  $\beta$ -blockers (104–107), (ii) pacemakers (108–110), (iii) left cervicothoracic sympathetic ganglionectomy (24,111,112), and,

most recently, (iv) internal cardioverter–defibrillator (ICD) (113,114). The mortality of untreated symptomatic patients with LQTS exceeds 20% in the year after their first syncopal episode and approaches 50% within 10 years of initial presentation (115). With institution of the classical therapy, this can be reduced to 2–4% in 5 years after initial presentation (105,115). Despite the lack of a placebo-controlled, randomized clinical trial, strong evidence supports the use of antiadrenergic interventions as the mainstay of therapy for most patients. The trigger for many life-threatening events appears to involve sudden increases in sympathetic activity (i.e. emotional or physical stress), and therefore, antiadrenergic therapy makes physiologic sense. The  $\beta$ -adrenergic blocking agents prevent new syncopal episodes in approximately 65–75% of patients (105). Suppression of complex ventricular arrhythmias (i.e. couplets and VT) seems desirable. Villain et al. (107) showed that a low incidence of cardiac events occurs in children with LQTS treated with  $\beta$ -blockers. In the 122 children studied, only four deaths occurred. Of the remainder, 111 children (92%) were treated with  $\beta$ -blockers alone, with no deaths and only five nonfatal cardiac events (4.5%) noted. None of these children had LQT1 mutations. Priori et al. (106) studied 335 patients treated with  $\beta$ -blockers for an average of 5 years and found 10% of LQT1 patients, 23% of LQT2 patients, and 32% of LQT3 patients had events while being treated, with the highest risk of events in LQT2 and LQT3 patients. Chatrath et al. (116) found that 25% of LQTS probands had cardiac events, with LQT1 most prevalent. In addition, they found that the highest rate of events occurred during treatment with atenolol, while propranolol appeared more protective. The addition of an IB agent (mexilitine) to  $\beta$ -blocker therapy may be helpful, particularly in patients with the LQT3 genotype (117). High-risk patients with drug-resistant, symptomatic VT are referred for left cardiac sympathetic denervation, which apparently provides additional protection (24,111,112). In addition, the use of cardiac pacing as an adjunct to  $\beta$ -blockers appears to be most rational in patients with evidence of pause-dependent or bradycardia-dependent arrhythmias (108–110). Symptomatic bradycardia due to LQTS or induced by  $\beta$ -blocker therapy should also be considered an indication for elective pacing.  $\beta$ -Blocker therapy is monitored with treadmill exercise testing, with the desired result a blunting of the heart rate response to exercise. However, Kaltman et al. (118) suggested that little difference occurs between pretreated and treated patients regarding QTc at any phase, QTc dispersion, or other QTc measures. Unfortunately, in some patients, this comes at the expense of excessive sinus bradycardia at rest and with minimal levels of exertion. Excessive fatigue, inattentiveness, and irritability may result in discontinuance of therapy by the patient. Compliance, especially

in the adolescent population, may be enhanced by returning the patient to a relatively normal lifestyle by the elimination of chronotropic incompetence with a pacemaker.

Other less time-tested therapies are also available. In some rare cases, torsade de pointes persists despite therapy with the classical modalities. The ICD has been used successfully in this setting (119,120). Until recently, it had not been considered to be the first-line therapy because shocks from the device can precipitate further emotional stress and set off a circuitous response of persistent malignant arrhythmias. However, the Multicenter Automatic Defibrillator Implantation Trial (MADIT), which demonstrated dramatic superiority of therapy with automatic implantable defibrillators over “best conventional therapy” in patients with coronary disease at high risk for ventricular arrhythmias (121), has made this therapeutic approach somewhat appealing. Automatic implantable defibrillators have been used more commonly in LQTS patients because of the results of the MADIT trial. However, whether this is the best approach is still not clear, and long-term data are needed to determine the answer to this question. Zareba et al. (114) have reported a 3-year follow-up analysis with 1.3% death in ICD patients versus 16% in non-ICD patients. Reports of efficacy in neonates have been published as well (113).

Another new approach to treating patients with LQTS is the so-called gene-specific approach. With the identification of the precise molecular defect in some patients with LQTS, specific mechanism-based therapies have been devised and small therapeutic trials were performed. Schwartz et al. (117) were the first to use this approach when they used the sodium-channel blocker mexilitine in patients with mutations in the sodium-channel gene *SCN5A* (LQT3). In these patients, the QTc was dramatically shortened in a statistically significant manner (Figure 51-5). Patients with potassium-channel mutations (HERG, LQT2) treated with mexilitine had no change in the QTc. However, no data currently exist that demonstrate clinical efficacy of this approach in either decreasing the number of syncopal events or improving the survival. Other sodium-channel blockers have had similar effects (27). Recently, Benhorin et al. (70) showed that flecainide shortened the QTc in patients with a D1790G *SCN5A* mutation while lidocaine was ineffective, suggesting that allele-specific therapies may be needed. Although the data are intriguing, use of sodium-channel blockers alone for patients with *SCN5A* mutations should still be considered experimental. Other gene-specific trials have also been performed with similar results. Compton et al. (122) used intravenous potassium to elevate the serum potassium to  $>4.8$  mEq/L in patients with LQT2 and found significant shortening of the QTc. Again, no data on survival or symptom improvement exist for this therapy, but this result has been confirmed (123). Etheridge et al. (124) showed that QTc reduction

**FIGURE 51-5** Mexiletine, a sodium channel blocker, shortens the QTc in two children with extreme QTc prolongation (>580 ms) and an *SCN5A* mutation.

may be large, and QT dispersion and T wave morphology improved, but outcome data were not available. Potassium-channel openers may have the same effect (125). Other gene-specific therapeutic approaches are currently being developed.

### 51.3.2 Brugada Syndrome

**51.3.2.1 Clinical Features.** This disorder is characterized by ST segment elevation in the right precordial leads ( $V_1$ – $V_3$ ) with or without right bundle-branch block (RBBB) (Figure 51-6) and episodic VF (Figure 51-7) (126). The first identification of the ECG pattern of RBBB with ST elevation in leads  $V_1$ – $V_3$  was reported by Osher and Wolff (127). Shortly thereafter, Edeiken (128) identified persistent ST elevation without RBBB in 10 asymptomatic males, and Levine et al. (129) described ST elevation in the right chest leads and conduction block in the right ventricle in patients with severe hyperkalemia. The first association of this ECG pattern with sudden death was described by Martini et al. (130) and later by Aihara et al. (131), and further confirmed in 1991 by Pedro and Josep Brugada (132), who described four patients with sudden death and aborted sudden death with ECGs demonstrating RBBB and persistent ST elevation in leads  $V_1$ – $V_3$ . In 1991, these authors characterized what they believed to be a distinct clinical and ECG syndrome (132,133). In some patients, the surface ECG appears normal, even in

familial cases. Provocation studies in the catheterization laboratory using ajmaline, flecainide, or procainamide will result in ST segment elevation in the right precordial leads in affected patients (134–137).

The finding of ST elevation in the right chest leads has been observed in a variety of clinical and experimental settings and is not unique or diagnostic of Brugada syndrome by itself. Situations in which these ECG findings occur include electrolyte or metabolic disorders, pulmonary or inflammatory diseases, and abnormalities of the central or peripheral nervous system. In the absence of these abnormalities, the term *idiopathic ST elevation* is often used and may identify Brugada syndrome patients (4). Two consensus conferences have been held to define the clinical signs, diagnostic approaches, therapies, and diagnostic studies (138–140).

The ECG findings and associated sudden and unexpected death have been reported as a common problem in Southeast Asia, where it most commonly affects men during sleep (141). This disorder, known as sudden unexplained death syndrome (SUDS) or sudden unexplained nocturnal death syndrome (SUNDS), has many names in Southeast Asia, including bangungut (to rise and moan in sleep) in the Philippines; non-laitai (sleep-death) in Laos; lai-tai (died during sleep) in Thailand; and pokkuri (sudden and unexpectedly deceased phenomena) in Japan (141,142). General characteristics of SUDS include young, healthy males in whom death occurs suddenly with a groan, usually during sleep late

**FIGURE 51-6** Brugada syndrome in a 4-year-old. Note the right ventricular conduction delay and ST segment elevation in leads  $V_1$  and  $V_2$ . Procainamide infusion worsened the ST elevation.

at night. No precipitating factors are identified, and autopsy findings are generally negative (143). Life-threatening ventricular tachydysrhythmias as a primary cause of SUDS have been demonstrated, with VF occurring in most cases (144).

**51.3.2.2 Brugada Syndrome and Arrhythmogenic Right Ventricular Dysplasia.** Controversy exists concerning the possible association of Brugada syndrome and arrhythmogenic right ventricular dysplasia (ARVD), with some investigators arguing that these are the same disorders or that at least one is a forme fruste of the other (145–150). However, the classical echocardiographic, angiographic, and magnetic resonance image (MRI) findings of ARVD are not seen in Brugada syndrome patients. In addition, Brugada syndrome patients typically are without the histopathologic findings of ARVD. Further, the morphology of VT/VF differs as noted in Table 51-2.

**51.3.2.3 Clinical Genetics.** Most of the families identified to date with Brugada syndrome have autosomal-dominant inheritance (151–154). It appears as if penetrance is reduced, as many patients have a normal ECG and no symptoms until provocation studies are performed or fever unmasks the ECG abnormalities (155,156). Although the number of families reported has been small, it is likely that this is due to underrecognition as well as premature and unexpected death.

**51.3.2.4 Molecular Genetics.** In animal studies, blockade of the calcium-independent 4-aminopyridine-sensitive transient outward potassium current ( $I_{to}$ ) results in surface ECG findings similar to that seen in Brugada

syndrome and includes elevated, downsloping ST segments (4), and occurs because of greater abbreviation in the epicardial action potential compared with the endocardium (which lacks a plateau phase). Loss of the action potential plateau (or dome) in the epicardium but not the endocardium would be expected to cause ST segment elevation and, because loss of the dome is caused by an outward shift in the balance of currents active at the end of phase I of the action potential (principally  $I_{to}$  and  $I_{Ca}$ ), autonomic neurotransmitters such as acetylcholine facilitate loss of the action potential dome by suppressing calcium current and augmenting potassium current, whereas  $\beta$ -adrenergic agonists (i.e. isoproterenol, dobutamine) restore the dome by augmenting  $I_{Ca}$ . Sodium-channel blockers also facilitate loss of the canine right ventricular action potential dome as a result of a negative shift in the voltage at which phase I begins (4,157). On the basis of this information, candidate genes ( $I_{to}$ ,  $I_{Ca}$ , and  $I_{Na}$ ) were selected for the study.

In 1998, our laboratory reported the findings on six families and several sporadic cases of Brugada syndrome (71) (Table 51-2). The families were initially studied by linkage analysis using markers to the known ARVD loci, and linkage was excluded. Candidate gene screening was performed and *SCN5A* was chosen for study, based on physiologic speculation (4). In three families, mutations in *SCN5A* (Figure 51-8) were identified (71). Since then, many groups have confirmed these findings and mutations have been identified throughout the channel topography. A second locus on chromosome 3 at 3p22–25 was

**FIGURE 51-7** Ventricular fibrillation in a patient with Brugada syndrome.

subsequently identified (158), but the gene has remained elusive.

In our original study, biophysical analysis of the mutants in *Xenopus* oocytes demonstrated a reduction in the number of functional sodium channels in some mutations, which promoted development of reentrant dysrhythmias, while in other mutations, sodium channels recovered from inactivation more rapidly than normal and were temperature dependent (155,156). In this case, the presence of both normal and mutant channels in the same tissue would be expected to promote heterogeneity of the refractory period, a well-established mechanism causing dysrhythmias. Inhibition of  $I_{Na}$  causes heterogeneous loss of the action potential dome in the right ventricular epicardium, leading to a marked dispersion of depolarization and refractoriness, an ideal substrate for development of reentrant dysrhythmias. Phase 2 reentry produced by the same substrate is believed to provide the premature beat necessary for initiation of the VT and VF responsible for symptoms

in these patients. Interestingly, however, Kambouris et al. (159) identified a mutation (R1623H) in essentially the same region of *SCN5A* as one of the original (T1620M) mutations, but the clinical and biophysical features of this mutation were found to be consistent with LQT3 and not Brugada syndrome. The same authors also demonstrated these mutant channels to have a propensity to inactivate without ever opening (i.e. closed-state inactivation), suggesting novel physiologic mechanisms can occur in a heterogeneous manner in similar regions of this ion channel (160). In some cases, LQT3 and Brugada syndrome occur in the same family (161,162).

**51.3.2.5 Therapy.** No good medical therapy has been clearly identified for these patients thus far. Belhassen et al. (163,164) have argued that quinidine has a role in chronic therapy for these patients, but this is based on a small number of clinical vignettes. In addition, Glatter et al. (165) suggested that sotalol may be effective. Currently, implantation of an ICD is the therapy of choice,

**FIGURE 51-8** Mutations in *SCN5A* in patients with Brugada syndrome versus those with long-QT syndrome.

but this remains controversial. The prognosis of these patients appears to be good (166). Ajiro et al. have suggested that late potentials on signal-averaged ECG irrespective of mutation (167). This is not confirmed by others (168,169).

### 51.3.3 Sudden Unexpected Nocturnal Death Syndrome

**51.3.3.1 Clinical Features.** SUNDS is a disorder that occurs in Southeast Asia, particularly Thailand, Cambodia, and the Philippines, as well as in Japan. The clinical features of this disorder are highlighted by the flamboyant names given this disease in the various Asian countries: lai-tai (died during sleep) in Thailand, pokkuri (sudden unexpected death at night) in Japan, and bangungut (moaning and dying during sleep) in the Philippines. SUNDS is the most common cause of “natural” death in these countries, typically occurring during sleep in males (141,142). The clinical features include an abnormal surface ECG with ST segment elevation in the right precordial leads (V<sub>1</sub>–V<sub>3</sub>), with or without RBBB. VF leads to the clinical symptoms of syncope, sudden death, and resuscitated sudden death. SUNDS is an allelic form of Brugada syndrome as the gene responsible for SUNDS is the same as the Brugada syndrome gene (Table 51-2).

**51.3.3.2 Genetics and Management.** SUNDS has not been considered an inherited disorder, but we have identified some families in which SUNDS is inherited as an autosomal dominant trait with mutations in *SCN5A*, the cardiac sodium-channel gene (170). The genetic findings have been confirmed by others (142,171). It is not currently clear why SUNDS afflicts men almost exclusively,

but it is certain that this is not transmitted in an X-linked manner, as male-to-male transmission occurs.

The management of SUNDS depends on implantation of an ICD in order to rapidly treat any episodes of VF. No medical therapy has proven effective for this disorder, but if quinidine therapy “pans out” for Brugada syndrome, it is likely that it would be used for SUNDS as well. Another important step necessary for optimal therapy of SUNDS is the screening of all family members by surface ECG testing. It is possible that provocation tests, similar to those described in Brugada syndrome, may be useful, but this has not been proven thus far.

### 51.3.4 SQT Interval Syndrome

**51.3.4.1 Clinical Features.** In 2000, Gussak et al. (172) identified a new familial clinical syndrome characterized by an abbreviated QTc interval (<300 ms), predisposition to life-threatening arrhythmias, and a high rate of sudden death. AF may occur and, on electrophysiologic evaluation, short refractory periods may be identified. Age of onset of symptoms may be young (<1 year of age) and in some cases, the syndrome may be responsible for SIDS.

**51.3.4.2 Genetics of Short-QT Syndrome.** Short-QT (SQT) syndrome was initially shown by Gussak et al. (172) to have autosomal-dominant inheritance. Multiple families and sporadic cases have been reported (172–176). Mutations in three ion-channel genes (SQT1, *HERG/KCNH2*; SQT2, *KvLQT1/KCNQ1*; SQT3, *Kir2.1/KCNJ2*) have been reported to date (173,174,176). In the case of SQT1, mutations dramatically increased I<sub>Kr</sub>, leading to heterogenous abbreviation of action potential duration and refractoriness

and reduced the affinity of the channels to  $I_K$  blockers. Bellocq et al. (173) performed functional studies on the *KCNQ1* mutations that revealed a pronounced shift of the half-activation kinetics, which led to a gain of function of  $I_{Ks}$  and repolarization shortening. In the case of the SQT3-causing mutations in *KCNJ2*, whole-cell patch-clamp studies of this *Kir2.1* ( $I_{K1}$ ) demonstrated a larger outward  $I_{K1}$  than wild type and shifting of peak current, as well as acceleration of the final phase of repolarization leading to shortened action potential duration. Clinically, this leads to tall and asymmetrical T waves, a finding that appears to be distinct for SQT3 (176).

**51.3.4.3 Therapy in SQT Syndrome.** As sudden death occurs commonly in this disorder, defibrillator implantation is indicated. Gaita et al. (177) evaluated the role of medical therapy, testing QTc interval response to flecainide, sotalol, ibutilide, and quinidine, with only quinidine producing QTc prolongation (normalization). However, no definitive treatment approaches have been described to date.

### 51.3.5 Right Ventricular Outflow Tract Tachycardia

**51.3.5.1 Clinical Features.** This rare form of VT occurs in the setting of an apparently normal, healthy individual who develops repetitive monomorphic VT arising from the right ventricular outflow tract (RVOT) (178–180). These VTs are characterized by left bundle-branch block (LBBB) morphology with an inferior frontal plane axis, which may be either leftward or rightward directed. Unlike ARVD and arrhythmogenic right ventricular cardiomyopathy (ARVC), which are also associated with LBBB/inferior axis VT, the ECG in normal sinus rhythm is typically normal. VT episodes tend to be characterized by frequent salvos of nonsustained VT or are separated by short periods of normal sinus rhythm and may be entirely asymptomatic. In some cases, however, catecholamines or exercise may provoke sustained episodes of VT. O'Donnell et al. (181) studied 33 patients with RVOT and compared them to 17 patients with ARVD/ARVC. Structural abnormalities were uniform by MRI in the ARVD/ARVC group, whereas many RVOT patients also had abnormalities in MRI. Electrophysiologic study showed a triggered automatic basis in 97% of RVOT cases, whereas the ARVD/ARVC patients displayed reentry in more than 80% of cases. Tada et al. showed that 9% of RVOT originated from the free wall, with 91% from the RVOT septum (182).

**51.3.5.2 Genetics.** No genetic data exist regarding RVOT VT. It is not known how often genetic inheritance occurs or what type of inheritance pattern occurs. At the molecular level, no gene has been identified.

**51.3.5.3 Management.** In some cases, these tachycardias appear to be adenosine sensitive, terminating with an intravenous bolus of adenosine. In other cases, verapamil has been reported to terminate the VT. Implantation of

an ICD may be considered in symptomatic patients with recurrent VT refractory to medical therapies.

### 51.3.6 Familial VT/CPVT

**51.3.6.1 Clinical Features.** This inherited form of VT was first described in detail by Rubin et al. (183) and is another form of VT that occurs in the absence of structural heart disease. Clinically, these patients present with frequent runs of nonsustained VT at rest (Figure 51-9), which may decrease or extinguish with exercise (183,184). In some cases, salvos of nonsustained VT may be incessant, causing palpitations, dizziness, or syncope. The ECG is usually normal during sinus rhythm, with a normal QT interval. Electrophysiologic evaluation may not consistently show inducible VT in these patients, suggesting that the mechanism in this dysrhythmia is not reentry as with more common forms of VT. Instead, it is believed that this form of inherited dysrhythmia is due to enhanced automaticity (i.e. an increased rate of electrical firing of a ventricular myocyte) or triggering (i.e. resulting from secondary depolarizations that occur during or immediately after repolarization).

Sumitomo et al. (185) described the ECG characteristics of CPVT and the clinical features in detail. The initial manifestations included young age at presentation (mean age of onset, 10.3 years), syncope (79%), cardiac arrest (7%), and family history (14%). Electrocardiograms demonstrated sinus bradycardia and normal QTc. The CPVT morphology included polymorphic (62%), polymorphic and bidirectional (21%), bidirectional (10%), and polymorphic with VF (7%).

**51.3.6.2 Genetics and Management.** This inherited tachydysrhythmia is transmitted as an autosomal-dominant trait (Table 51-2) (186). Mutations in *RyR2* have been identified as causative in CPVT (41,187–189). In addition, mutations of the calsequestrin gene have been found in CPVT (162a,190,191); they appear to be relatively uncommon, but the incidence and prevalence are not known. The therapy of this disorder appears to rely on the use of  $\beta$ -adrenergic blocking agents, which effectively suppress this rhythm disturbance. However, Sumitomo et al. showed complete  $\beta$ -blocker control in only 31% of cases (185). In addition, the use of class I and class III antiarrhythmics have reportedly been successful in treating this disorder. Sumitomo et al. also showed that calcium-channel antagonists partially suppressed CPVT in some familial autosomal-dominant cases. The use of ICDs has not been reported in this disorder, but this is certainly a likely option in familial or difficult cases.

### 51.3.7 Bidirectional VT

**51.3.7.1 Clinical Features.** Bidirectional VT occurs as an acquired disorder as well as an inherited abnormality. The acquired form occurs secondary to digitalis intoxication

**FIGURE 51-9** Monomorphic ventricular tachycardia (200 beats/min).

(192), whereas the inherited form occurs in families (193–195). This latter form of VT occurs in the absence of drugs or structural heart disease. Clinically, this disease appears to be catecholamine sensitive (196–199), with increased adrenergic stimulation inducing polymorphic ventricular premature complexes followed by directional and polymorphic VT (196). Owing to this characteristic feature, the disorder has also been termed *catecholaminergic polymorphic VT*. Many patients present during the first decade of life with syncope or sudden cardiac death although in many cases, the individual may be asymptomatic. Bidirectional VT has a characteristic ECG appearance that includes VT with an RBBB morphology, alternation in the frontal plane QRS axis from  $-60^\circ$  to  $-80^\circ$  to  $+120^\circ$ , and a rate of 140–200 beats/min (200). This form of VT may be confused with a supraventricular rhythm arising from above the AV node, but several differentiating features are known. These include dissociation of the atria from the ventricles during tachycardia and the ability to identify the His bundle during tachycardia (195), which both occur with bidirectional VT.

**51.3.7.2 Genetics and Management.** This disorder appears to be transmitted as an autosomal-dominant trait with variable penetrance (Table 51-2). A family history of syncope or sudden death is reported in 30% of cases. The therapy for this disorder is not completely clarified, but it appears as if exercise or increase in atrial rate by atrial overdrive pacing (194,195) suppresses the VT. Recurrence of the dysrhythmia has been prevented by  $\beta$ -blockers (193). Fisher et al. (197) have reported 25 years of follow-up in patients with this form of VT in which medical therapy, predominantly  $\beta$ -blockers, was successfully based on serial exercise-pharmacologic

testing. In these patients, early identification of exercise- or catecholamine-induced dysrhythmias, as demonstrated on exercise stress tests predominantly, led to successful therapy.

Swan et al. (201) initially mapped a gene for malignant polymorphic VT in two families with structurally normal hearts to chromosome 1q42–q43 (Table 51-2). Previously, based on our final common pathway hypothesis, we speculated that all ventricular tachyarrhythmia disorders would be due to ion-channel abnormalities (i.e. ion channelopathy) and suggested that identification of this gene would help to clarify this mystery. As noted, mutations in RyR2 were identified, and subsequently mutations in calsequestrin were also found.

## 51.4 PRIMARY ABNORMALITIES IN CARDIAC RHYTHM: SUPRAVENTRICULAR DYSRHYTHMIAS

### 51.4.1 Familial AF

**51.4.1.1 Clinical Features.** AF is considered the most common sustained dysrhythmia worldwide (Figure 51-10) and is believed to be the most common cause of embolic stroke, accounting for 75,000 strokes per year in the United States (202). Currently, there are more than 3 million cases of AF in the United States, with an overall prevalence of 0.5–1%, increasing to approximately 10% in individuals older than the age of 70 years. AF accounts for about one-third of strokes in people over the age of 65 years and leads to more hospital admissions than any other dysrhythmia (203). However, AF can also occur in children and in fetal life (204).

**FIGURE 51-10** Atrial fibrillation with its irregularly irregular rhythm and fibrillation pattern, which is well seen in the right chest leads (V3R, V4R) and rhythm strip.

**51.4.1.2 Genetics.** Familial AF was initially considered to be rare, but Brugada and Brugada (205) identified multiple families with familial AF from Spain and noted the penetrance to be high. Generally, the disease was found to be chronic, but some individuals presented with paroxysmal AF, some having palpitations. Left atrial dilation has developed in select individuals; syncope and dyspnea also occur in these patients. This disorder appears to be inherited as an autosomal-dominant trait, and many of these patients develop AF very early in childhood (204,206–208). Brugada et al. (152) identified the first locus for familial AF to chromosome 10q22–q24 (Table 51-2), and genetic heterogeneity was subsequently identified. The first gene for familial AF was found to be *KCNQ1*, the same gene causing LQT1 (209). This gene, located in chromosome 11p15.5, causes AF via gain-of-function mutations, in contrast to the dominant-negative or loss-of-function mutation that causes LQT1. In addition, *minK*, the other subunit associated with  $I_{Ks}$ , was shown by Lai et al. (210) to have a polymorphism (38G) that is associated with disease and possibly plays a role in control of AF pathogenesis. More recently, Yang et al. (211) identified mutations in *KCNE2/MiRP1* causing AF via a gain of function. Finally, a locus on chromosome 6q14–16 has been shown to be another AF locus (212).

## 51.4.2 Wolff–Parkinson–White Syndrome

**51.4.2.1 Clinical Features.** In the normal heart, the atria and ventricles are electrically connected via a single pathway through the AV node. In Wolff–Parkinson–White (WPW) syndrome (213), an accessory AV

bypass pathway is present, creating the substrate for tachydysrhythmias (214). The electrical conduction properties of accessory pathways in WPW syndrome are more like those seen in ventricular myocardium than in AV nodal tissue and may conduct very rapidly with a short refractory period (215). During sinus rhythm, ventricular excitation occurs via the accessory pathway before excitation through the AV node, a process referred to as *preexcitation*. It is this preexcitation that is responsible for the characteristic ECG findings of a short PR interval and the so-called delta wave, a slurring of the upstroke of the QRS complex (Figure 51-11).

The most common dysrhythmia seen in patients with WPW syndrome is orthodromic AV reciprocating tachycardia (AVRT), which uses the AV node as the antegrade limb and the accessory pathway (i.e. bypass tract) as the retrograde limb (216). This tachydysrhythmia commonly causes palpitations, chest pain, dizziness and lightheadness, shortness of breath, and, in some cases, syncope. When sustained, AVRT may precipitate onset of AF, which under certain circumstances may be life-threatening because of its ability to rapidly conduct via the accessory pathway, inducing VF. These patients are, therefore, at increased risk of sudden death.

**51.4.2.2 Genetics and Management.** Although most cases of WPW syndrome are believed to be sporadic, autosomal-dominant inherited WPW syndrome is well described (217–219). The incidence of preexcitation in first-degree relatives has been reported to be <1%, with the prevalence in the general population thought to be approximately 0.15% (215,219). Notably, patients with multiple pathways have an increased prevalence

**FIGURE 51-11** Electrocardiogram of a 15-year-old female with Wolff–Parkinson–White syndrome. The electrocardiographic features include a short P–R interval and delta wave.

of preexcitation in first-degree relatives, approximately 1.7%. WPW syndrome may also occur in the setting of congenital heart disease, particularly Ebstein anomaly, or myocardial disease (i.e. hypertrophic cardiomyopathy [HCM]). It is not clear whether WPW in this circumstance has increased familial incidence. The permanent form of junctional reciprocating tachycardia (PJRT), in which a septal accessory pathway is present and has decremental properties similar to the AV node, appears to have familial inheritance as well but is probably uncommon. Neither pure WPW syndrome nor familial PJRT has been deciphered from a genetic standpoint. However, a form of WPW has been genetically identified.

In WPW syndrome families with WPW associated with left ventricular hypertrophy (LVH)/HCM, a gene was mapped to chromosome 7q3 (220), but the gene remained elusive until Gollob et al. (221) and Blair et al. (222) identified the AMP-kinase gene *PRKAG2* as causative (Table 51-2). This gene was cloned in 2000 (223) and was shown to act as a major regulator of cellular ATP levels and to protect cells against stresses that cause ATP depletion. Since its initial description, multiple mutations have been identified in patients with WPW with or without LVH (224–228). Murphy et al. (226) showed that 78% of patients with mutations had LVH, there was 91% survival at 12 years of follow-up, and progressive conduction disease occurred in 40%. Some patients also have skeletal myopathy. Murine models have been made that demonstrate this disease to be equivalent to a glycogen storage disease (224,229). Loss of function of the gene was also noted.

The current first-line therapy for WPW is radiofrequency ablation, which, in most cases, permanently disrupts the accessory pathway (230). In the small percentage of patients not undergoing radiofrequency ablation, medical therapy may be used.

## 51.5 PRIMARY CONDUCTION ABNORMALITIES

### 51.5.1 Lev-Lenegre Progressive Cardiac Conduction Disease

**51.5.1.1 Clinical Features.** This syndrome, also known as progressive cardiac conduction defect (PCCD), is among the most common cardiac conduction disorders in the world and represents the major cause for pacemaker implantation worldwide, at 0.15 pacemaker implantations per 1000 inhabitants per year in developed countries (72). PCCD is characterized by progressive worsening of cardiac conduction through the His–Purkinje system, resulting in RBBB or LBBB and widening of the QRS complex (231–233). Patients with this disorder ultimately develop complete AV block (Figure 51-14) and, in many instances, present with syncope or sudden death. Etiologically, PCCD has been considered to be a primary degenerative disease or an exaggerated age-related process, in which sclerosis of the conduction system occurs.

**51.5.1.2 Genetics.** The first gene for PCCD was mapped to chromosome 19q13.3 (Table 51-2) in families with autosomal dominantly transmitted disease (234,235). Genetic heterogeneity was identified when

**FIGURE 51-12** Complete atrioventricular block in an individual with bradycardia.

Schott et al. demonstrated linkage to chromosome 3p21 and identified mutations in the cardiac sodium-channel gene *SCN5A* (72) (Table 51-2). This gene had previously been shown to cause a form of LQTS (LQT3) as well as Brugada syndrome (63,64,71). Other supportive evidence of *SCN5A* mutations causing AV block have been reported. Miura et al. (236) identified *SCN5A* mutations in congenital LQT and 2:1 AV block, while Shirai et al. (237) showed that mutations in this gene may cause overlapping features of Brugada syndrome and cardiac conduction disease. Tan et al. (238) showed that mutations in *SCN5A* result in isolated conduction system disease as well, and this was confirmed by Wang et al. (239). In addition, Viswanathan et al. (240) showed that a common *SCN5A* polymorphism (H558R) mitigates the effects of mutations on channel function and the clinical response.

**51.5.1.3 Management.** Patients with PCCD require pacemaker therapy once bradycardia occurs. In cases in which syncope precedes diagnosis, immediate implantation is appropriate. Before pacemaker implantation, serial ECGs and Holter monitor studies are necessary for close monitoring.

### 51.5.2 Familial Complete Atrioventricular Heart Block

This disorder, when familial, presents with adult onset (age 20–50 years) and has an autosomal-dominant inheritance pattern (241–243). Approximately 50 families have been identified with this disorder and, in all cases, transmission is consistent with autosomal-dominant inheritance with full penetrance and variable

expression. Whether all these conditions represent a single disorder is not known. The common presentation of this disease includes one of the following: (i) RBBB alone, (ii) left axis deviation (LAD) alone, (iii) RBBB plus LAD, or (iv) complete heart block (Figure 51-12). In addition, AV block has been associated with dilated cardiomyopathy (DCM) and skeletal myopathy, and several genetic loci have been identified for those cases (Sections 51.6.5 and 51.7.3). As previously noted, another gene has been mapped to chromosome 19q13 in a family with AV block (Table 51-2) but without DCM (234), while the gene for Lev-Lenegr PCCD and for isolated conduction disease has been found to be the cardiac sodium-channel gene *SCN5A* (72,238,239) (Table 51-2).

### 51.5.3 Familial Total Atrial Standstill

**51.5.3.1 Clinical Features.** Atrial standstill is characterized by the complete absence of spontaneous atrial electrical activity and inability to pace the atria. In addition to loss of electrical activity, there is a loss of mechanical function of the atria documented by absence of A waves on jugular venous pulse and right atrial pressure tracing, and absence of atrial contraction as detected by echocardiography. Primary atrial standstill can occur as sporadic cases or in families. Familial cases have been reported in an isolated community having a high rate of inbreeding (244–246). Familial atrial standstill can be associated with other cardiac abnormalities. Ebstein anomaly (ventricular displacement of the tricuspid valve) has been reported in one family with persistent atrial standstill (247). Certain types of muscular dystrophy

(e.g. Emery–Dreifuss muscular dystrophy (EDMD)) and Kugelberg–Wielander syndrome can present with atrial standstill. These disorders are discussed in further detail below.

Atrial standstill and abnormal sinus node function are common dysrhythmias in familial cases of amyloidosis. Often other systemic effects of amyloidosis, such as peripheral neuropathy, cardiomyopathy, or renal dysfunction, are not seen in these cases. Histologic evidence of amyloid deposits may be identified in atrial or ventricular myocardium (248).

The clinical symptoms of atrial standstill, whether primary or secondary to a systemic disease, may be due to absence of atrial activity or to intermittent atrial tachydysrhythmias. Patients may present with bradycardia due to loss of atrial activity or with palpitations, presyncope, dyspnea, or chest pain as a result of atrial tachydysrhythmias. A high rate of unexplained sudden death has been reported (244,246). Loss of atrial mechanical function may predispose to the development of atrial thrombi, and cerebral and peripheral emboli are reported in up to 30% of cases (244,247).

**51.5.3.2 Genetics and Management.** The mode of inheritance is not known with certainty as there are few reports of large affected families, but it is most likely autosomal dominant (244). No gene has been identified thus far (Table 51-2). Treatment consists of permanent ventricular pacing for symptomatic bradycardia and chronic anticoagulation to prevent formation of atrial thrombi.

### 51.5.4 Sinus Node Dysfunction/Sick Sinus Syndrome

**51.5.4.1 Clinical Features.** Congenital absence of sinus rhythm (249) or sinus node dysfunction (250,251) occurs in familial forms. The clinical presentation is generally due to symptomatic bradycardia, but it also may be associated with paroxysmal AF and other atrial tachydysrhythmias. Histologic data are limited, but one report of a single member of a family who suffered sudden death showed mononuclear cell infiltration of the sinus node, fibrosis of the sinus and AV nodes and atrial tissue, and atrophy of the right and left bundle branches (252).

**51.5.4.2 Genetics and Management.** The inheritance pattern of familial congenital absence of sinus node function is autosomal dominant with a high degree of penetrance (Table 51-2). The gene for this disorder remains unknown. However, Benson et al. (73) identified homozygous mutations in the cardiac sodium-channel gene *SCN5A* in individuals with sick sinus syndrome.

Treatment consists of permanent pacing for symptomatic bradycardia, and, unlike persistent atrial standstill, in which the atria are unable to be paced because of inability to produce electrical excitation, atrial or dual-chamber pacing may be used. If AF is a prominent

feature, antiarrhythmic medications and/or chronic anticoagulation may be indicated.

## 51.6 FAMILIAL DYSRHYTHMIAS ASSOCIATED WITH MYOCARDIAL DISEASE

### 51.6.1 Hypertrophic Cardiomyopathy

HCM is characterized by myocardial hypertrophy with a wide spectrum of symptoms, including dyspnea, chest pain, and syncope (253). The annual mortality rate was initially reported to be 2–4%, primarily due to sudden death and often occurring in asymptomatic individuals, but is now believed to be 0.1% per year. This disorder is considered to be the leading cause of sudden death in the young and in athletes (254). The annual incidence of sudden death is higher in younger patients with familial HCM than in the elderly. The diagnosis is based on typical clinical features and the demonstration of unexplained left ventricular, right ventricular, or biventricular hypertrophy on two-dimensional echocardiography. The LVH is commonly asymmetrical, localized to the septum, but may involve the entire ventricle in a concentric pattern (Figure 51-13). Isolated right ventricular hypertrophy occurs in fewer than 5% of cases. Isolated apical hypertrophy is rare except in Japan, where it is claimed to account for 20–30% of the cases, or in elderly patients. Dynamic outflow tract obstruction occurs in about 30% of patients. Histologically, the myocardial hypertrophy consists of myocyte hypertrophy, cellular and myofibrillar disarray, and myocardial fibrosis, and one of the hallmarks of familial HCM is myocyte and myofibrillar disarray (255).

**FIGURE 51-13** Echocardiogram demonstrating hypertrophic cardiomyopathy with left ventricular posterior wall and interventricular septal hypertrophy. LV, left ventricle; RV, right ventricle.

**51.6.1.1 Mapping of *FHC* Genes.** The first gene for familial hypertrophic cardiomyopathy (FHC) was mapped to chromosome 14q11.2–q12 using genome-wide linkage analysis in a large Canadian family (256). Soon after, FHC locus heterogeneity was reported (257–259) and subsequently confirmed by Watkins et al. when they mapped the second FHC locus to chromosome 1q3 (260), and by Thierfelder et al. (261), who mapped the third locus to chromosome 15q2 (261) (Table 51-3). Carrier et al. (262) mapped the fourth FHC locus to chromosome 11p11.2. Five other loci were subsequently reported, located on chromosomes 7q3 (220), 3p21.2–3p21.3, (263), 12q23–q24.3 (264), 15q14 (265), and 2q31 (266) (Figure 51-14). Several other families were not linked to any known FHC loci, indicating the existence of additional FHC-causing genes. These genes have been identified in patients presenting late in childhood or adulthood and not in neonates, infants, and very young children.

**51.6.1.2 Gene Identification in FHC.** Most of the disease genes encode proteins that are part of the sarcomere (i.e. a sarcomyopathy), which is a complex structure with an exact stoichiometry and multiple sites of protein–protein interactions (267,268). The encoded proteins (Figure 51-16) include three myofilament proteins,  $\beta$ -myosin heavy chain (269,270) and ventricular myosin essential light chain 1 and ventricular myosin regulatory light chain 2 (263); four thin filament proteins, cardiac actin (265), cardiac troponin T (267), cardiac troponin I (264), and  $\alpha$ -tropomyosin (267); and finally one myosin-binding protein, the cardiac myosin-binding protein C (271,272). Titin and muscle LIM proteins, both Z-disk proteins, were described as well (266) (Table 51-3). Each of these proteins is encoded by multigene families that exhibit tissue-specific, developmental, and physiologically regulated patterns of expression. More recently, mutations in the *PRKAG2* gene encoding AMP-kinase on chromosome 7q3 (222,273), and the *LAMP-2* gene on Xq28 have been shown to be metabolic causes of LVH (224).

### 51.6.1.3 Thick-Filament Proteins (Figure 51-14).

**51.6.1.3.1 Myosin Subunits.** Myosin is the molecular motor that transduces energy from the hydrolysis of ATP into directed movement and that, by doing so, drives sarcomere shortening and muscle contraction. Cardiac myosin consists of two heavy chains (MyHC) and two pairs of ventricular light chains (MLC), referred to as essential (or alkali) light chains (MLC-1) and regulatory (or phosphorylatable) light chains (MLC-2) (274). The myosin molecule is highly asymmetrical, consisting of two globular heads joined to a long rod-like tail. The light chains are arranged in tandem in the head–tail junction. Their function is not fully understood. Neither myosin light chain type is required for the adenosine triphosphatase (ATPase) activity of the myosin head, but they probably modulate it in the presence of actin and contribute to the rigidity of the neck, which is hypothesized to function as a lever arm for

generating an effective power stroke. Mutations have been found in the heavy chains and in the two types of ventricular light chains.

Concerning the heavy chains, the  $\beta$  isoform ( $\beta$ -MyHC) is the major isoform of the human ventricle and of slow-twitch skeletal fibers. It is encoded by *MYH7*. At least 50 mutations have been found in unrelated families with FHC, and three hot spots for mutations have been identified, including codons 403, 719 and 741. All but three of these mutations are missense mutations located in the head or in the head–rod junction of the molecule (275). The three exceptions are two 3 bp deletions that do not disrupt the reading frame (codon 10, codon 930) and a 2.4 kb deletion in the 3' region. In the kindred with the latter mutation, only the proband developed clinical evidence of HCM, and in this case, it occurred at a very late age of onset (59 years).

Animal models were initially reported by Vikstrom et al. (276) and Geisterfer-Lowrance et al. (277). The mice produced by these groups developed HCM-like disease. Heterozygotes have been produced with the Arg403Gln mutation and have been shown to have normal survival, whereas homozygotes had premature death, mimicking the human mutations. Fatkin et al. (278) demonstrated neonatal cardiomyopathy in homozygotes. In addition, Bevilacqua et al. (279) demonstrated QT dispersion in these animals, whereas Berul et al. (280) showed gender differences in the electrophysiologic abnormalities seen in these animals.

As for the light chains, the isoforms expressed in the ventricular myocardium and in the slow-twitch muscles are the so-called ventricular myosin regulatory light chain (MLC-2s/v), encoded by *MYL2*, and the ventricular myosin essential light chain (MLC-1s/v), encoded by *MYL3*. They both belong to the superfamily of EF-hand proteins. Two missense mutations have been reported in *MYL3* and five in *MYL2*.

**51.6.1.3.2 Myosin-Binding Protein C.** Myosin-binding protein C (MyBP-C) is a part of the thick filaments of the sarcomere, being located at the level of the transverse stripes, 43 nm apart, seen by electron microscopy in the sarcomere A band. Its function is uncertain, but it is believed to play both structural and regulatory roles. Partial extraction of the cardiac isoform (cMyBP-C) from rat-skinned cardiac myocytes and rabbit skeletal muscle fibers has been shown to alter  $\text{Ca}^{2+}$ -sensitive tension (281). In addition, the phosphorylation of cMyBP-C was shown to alter myosin cross-bridges in native thick filaments, suggesting that cMyBP-C can modify force production in activated cardiac muscles.

cMyBP-C is encoded by the *MYBPC3* gene (272,282), which has three distinct regions that are specific to the cardiac isoform: the  $\text{NH}_2$ -terminal domain C0 immunoglobulin I (IgI), containing 101 residues; the MyBP-C motif, a 105-residue stretch linking the C1 and C2 IgI domains; and a 28-residue loop inserted in the C5 IgI domain (283). It was later shown that cMyBP-C is

## MOLECULAR GENETICS OF HCM

**FIGURE 51-14** Loci, genes, and proteins responsible for familial hypertrophic cardiomyopathy. All genes causing HCM encode proteins of the sarcomere.

specifically expressed in the heart during human and murine development (284,285).

Approximately 30 MYBPC3 mutations have been identified in unrelated families with FHC. In the majority of cases, the mutations result in aberrant transcripts that are predicted to encode COOH-terminal truncated cardiac MyBP-C polypeptides lacking at least the myosin-binding domain. Of the remaining reported mutations, mutated or deleted proteins occur without disruption of the reading frame; most of these are missense mutations (exons 6, 17, 21, and 23), but a splice donor site mutation (intron 27) and an 18-residue duplication (exon 33)

have also been reported (271,272,286–289). In addition, three mutations are predicted to produce either a mutated protein or a truncated one: two are missense mutations in exon 15 and 17 and the other is a branch-point mutation in intron 23. It has been suggested that most mutations result in a dominant-negative action of the mutant protein. Another possibility is defective processing and rapid degradation of partially glycosylated protein. This rapid degradation of a truncated protein may be a critical step preventing myofibrillogenesis, with filament formation (rather than the function of assembled filaments) being disturbed (286,290,291).

A mouse model was reported by McConnell et al. (292), in which mice expressing altered forms of *MYBPC3* were produced. The engineered mutations encoded truncated forms of MyBP-C in which the cardiac MyHC-binding and titin-binding domain were replaced with novel amino acid residues. Homozygous mice exhibited neonatal onset of a progressive DCM with myocyte hypertrophy, myofibrillar disarray, fibrosis, and dystrophic calcification on histopathology. Left ventricular dilation with reduced contractility was noted on echocardiography in the neonatal period, but myocardial hypertrophy and diastolic dysfunction developed later in the life of these animals. Previously, Yang et al. (293) reported a mouse model of HCM due to mutant MyBP-C, and this clinical phenotype was more similar to the human disorder. Here, however, the transgenic animals had very high levels of mutant gene (driven by the  $\alpha$ -MHC promoter) and diminished wild-type gene expression to very low levels.

**51.6.1.4 Thin-Filament Proteins (Figure 51-14).** The thin filament contains actin, the troponin complex, and tropomyosin. The troponin complex and tropomyosin constitute the  $\text{Ca}^{2+}$ -sensitive switch that regulates the contraction of cardiac muscle fibers. Mutations were found in  $\alpha$ -tropomyosin ( $\alpha$ -TM) (267) and in two of the subunits of the troponin complex: cardiac troponin I (cTnI), the inhibitory subunit, and cardiac troponin T (cTnT), the tropomyosin-binding subunit (264,267). Recently, actin mutations have also been reported (265).

$\alpha$ -TM is encoded by *TPM1*. The cardiac isoform is expressed both in the ventricular myocardium and in fast-twitch skeletal muscles (294). It shares the overall structure of other tropomyosins that are rod-like proteins that possess a simple dimeric  $\alpha$ -coiled-coil structure in parallel orientation along their entire length. Four missense mutations were initially described in unrelated FHC families. Two of them, A63V and K70T, are located in exon 2b within the consensus pattern of sequence repeats of  $\alpha$ -TM and could alter tropomyosin binding to actin. Mutations D175N and E180G are both located within constitutive exon 5, in a region near the C190 and near the calcium-dependent troponin T-binding domain. This appears to be a relatively rare cause of HCM. Michelle et al. (295) later demonstrated that the known  $\alpha$ -TM mutations rely on the calcium-sensitizing effects of these mutations to define the severity of disease.

cTnT is encoded by *TNNT2*. In human cardiac muscle, multiple isoforms of cTnT have been described that are expressed in the fetal, adult, and diseased heart, and that result from alternative splicing of the single gene *TNNT2* (296,297). The precise physiologic relevance of these isoforms is currently poorly understood, but the organization of the human gene has been partially established (298,299), thus allowing precise identification of the position of the mutations within exons, including those alternatively spliced during development.

cTnI is encoded by *TNNI3*. The cTnI isoform is expressed only in the cardiac muscles (300). Cooperative binding of cTnI-actin-tropomyosin is a unique property of the cardiac variant (301). A small number of troponin I mutations have been identified in FHC, with others found in patients with restrictive physiology mimicking restrictive cardiomyopathy (265a).

$\alpha$ -Cardiac actin was also identified as a cause of FHC. Mogensen et al. (265) studied a family with heterogeneous phenotypes, ranging from asymptomatic with mild hypertrophy to pronounced septal hypertrophy and left ventricular outflow tract obstruction. Using linkage analysis and mutation screening, the gene was mapped to chromosome 15q14 with a LOD score of 3.6, and a missense mutation (G $\rightarrow$ T in position 253, exon 5) resulted in an Ala295Ser amino acid substitution. The mutation is localized at the surface of actin in proximity to a putative myosin-binding site. This mutation, which causes FHC, differs from the two mutations reported to cause DCM, which were localized in the immobilized end of actin that cross-binds to the anchor polypeptides in the Z-bands (302). It appears that mutations near the dystrophin-binding region result in DCM, whereas mutations affecting the sarcomeric end result in an HCM phenotype.

**51.6.1.5 Genotype-Phenotype Relations in FHC.** The pattern and extent of LVH in patients with HCM vary greatly even in first-degree relatives, and a high incidence of sudden deaths is reported in selected families. An important issue, therefore, is to determine whether the genotype heterogeneity observed in FHC accounts for the phenotypic diversity of the disease. However, the results must be seen as preliminary, because the available data relate to only a few hundred individuals. Several concepts nevertheless begin to emerge, at least for mutations in the *MYH7*, *TNNT2*, and *MYBPC3* genes. For *MYH7*, it is clear that prognosis for patients with different mutations varies considerably (303). For example, the R403Q mutation appears to be associated with markedly reduced survival, whereas some others, such as V606M, appear more benign (Figure 51-15). The disease caused by *TNNT2* mutations is usually associated with a 20% incidence of nonpenetrance, a relatively mild (and sometimes subclinical) hypertrophy, but a high incidence of sudden death that can occur even in the absence of significant clinical LVH (304,305). However, one family with a *TNNT2* mutation reportedly had complete penetrance, and echocardiographic data showed a wide range of hypertrophy and there was no sudden cardiac death (298). Thus, more data are needed before final conclusions are drawn. Mutations in *MYBPC3* seem to be characterized by specific clinical features, with a mild phenotype in young subjects, a delayed age at onset of symptoms, and a favorable prognosis before the age of 40 years (271,304–307).

Genetic studies have also revealed the presence of clinically healthy individuals carrying a mutant allele (no matter which gene is affected), which is associated

**FIGURE 51-15** Kaplan-Meier survival curve in hypertrophic cardiomyopathy comparing mutations of  $\beta$ -myosin heavy chain, cardiac troponin T, and  $\alpha$ -tropomyosin.

in first-degree relatives with a typical phenotype of the disease. Several mechanisms could account for the large variability of the phenotypic expression of the mutations: the role of environmental differences and acquired traits (e.g. differences in lifestyle, risk factors, and exercise), and finally, the existence of modifier genes and/or polymorphisms that could modulate the phenotypic expression of the disease. The only significant results obtained so far concern the influence of the angiotensin I-converting enzyme insertion/deletion polymorphism. Association studies showed that, compared to a control population, the D allele is more common in patients with HCM and in patients with a high incidence of sudden cardiac death (308,309). It was recently shown that the association between the D allele and hypertrophy is observed in the case of MYH7 R403 codon mutations, but not with MYBPC3 mutation carriers (310), raising the concept of multiple genetic modifiers in FHC.

**51.6.1.5.1 Elucidation of the Pathogenesis from Genetic Models.** On the basis of in vitro and in vivo studies in genetic animal models of HCM, it now appears that the primary defect is impaired contractility. Analysis of a human heart from a patient with the Arg403Gln mutation showed that the ratio of myosin to actin was normal (311), indicating there is no deficiency of the  $\beta$ -MHC protein. All the responsible mutant genes encode for a sarcomeric protein and appear, in some way, to impair systolic contraction or diastolic relaxation. In feline adult cardiac myocytes, in which  $\beta$ -MHC is the predominant myosin form, expression of human mutant  $\beta$ -MHC gene, Arg403Gln, was associated with sarcomere disassembly (312). Expression of the human mutant troponin T in this model also induced sarcomere disassembly and was associated with impaired rate of

cell shortening as detected by laser (313). Furthermore, it was shown that the expressed mutant protein was incorporated into the sarcomere. In a transgenic mouse, expression of troponin T gene (cTnT-Gln92) (314) exhibited sarcomere disarray, increased fibrous tissue, and sudden death, but only minimal hypertrophy. In this model, it was also shown that increased expression of the mutant protein was associated with a more severe phenotype, confirming the mutant protein has a dominant-negative effect as expected. These results have been confirmed by several investigators (276,277,312,315). Expression of the mutant MyHC gene or the troponin gene in the mouse has, in general, been associated with less hypertrophy than expected (314). Recently, a transgenic rabbit model (rabbit has  $\beta$ -MHC as its cardiac myosin) has been developed expressing the  $\beta$ -MHC (Arg403Gln) mutation, which exhibits sarcomere disarray, hypertrophy, and increased fibrous tissue virtually identical to that observed in humans (316).  $\alpha$ -TM mutations in an animal model caused cardiac dysfunction as well (317). Thus, the overall postulated pathogenesis of FHC may be summarized briefly as follows: the mutant protein is incorporated into the sarcomere and acts as a “poison peptide” that impairs contractility of that particular cell, which, in turn, provides the stimulus for the mitogenic response (probably several growth factors) of compensatory hypertrophy. The growth stimulus, as in acquired disorders, appears highly localized and mediated by autocrine or intracrine factors, given that the hypertrophy is localized in many patients, primarily to the interventricular septum. The growth factors also stimulate fibroblast proliferation and increased matrix formation. The relationship between the hypertrophy and increased fibrous tissue response to sudden death and arrhythmias remains to be determined. It is postulated that the fibrous tissue leads to delayed electrical conduction and predisposes to arrhythmias and sudden death. The future elucidation of the molecular basis for the pathogenesis of this disease, however, must provide a rationale for three puzzling, consistent features of the pathology of FHC: (i) predominance of hypertrophy in the septum, (ii) sarcomere and myocyte disarray, and (iii) the supernormal systolic function. The diastolic stiffness or decreased compliance is expected with hypertrophy whether it is primary or compensatory, but these other features are not seen in compensatory hypertrophy associated with myocardial infarction or pressure overload.

**51.6.1.6 Management.** Medical therapy is typically indicated (318). The most commonly used medications include  $\beta$ -blockers and calcium-channel blockers. Good hydration status is also important: antiarrhythmic agents are used when necessary; and poorly controlled ventricular dysrhythmias or syncope may lead to ICD implantation. In cases in which severe obstruction occurs, myomectomy or pacemaker implantation (DDD mode) has been utilized. More recently, alcohol ablation has

been employed in adults. Cardiac transplantation may be necessary in cases with dilation and systolic dysfunction.

### 51.6.2 Neonatal HCM

Clinically, this appears to be the same disorder as that seen in older children and adults (319). Echocardiograms and ECGs tend to mimic the findings described for adults with HCM. However, the underlying etiologies appear to differ from the sarcomeric gene-related disorders of adults. In the neonate and infant with HCM, abnormalities of mitochondrial function and metabolic disorders tend to predominate. In addition, genetic syndromes are common in this age group as well. Mott et al. (320) have demonstrated that Noonan syndrome, mitochondrial myopathies, and metabolic disorders such as glycogen storage diseases predominate, along with abnormalities of fatty acid oxidation. Although sarcomeric gene mutations could be involved as well, few patients have been described to date in the literature. Instead, it is likely that the sarcomere is secondarily affected by the mitochondrial and metabolic abnormalities, which probably create an energy production–utilization mismatch (224,321–323).

Finally, neonates with a dilated form of HCM with combined systolic and diastolic dysfunction are well described. In some cases, deep endomyocardial trabeculations are noted, consistent with left ventricular non-compaction (324,325) (Figure 51-16). Males with this abnormality have been shown, in some cases, to carry mutations in G4.5, an X-linked gene (*Xq28*) that encodes a novel protein called tafazzin (326–328) (Table 51-3), which is thought to function as an acyltransferase. Clinically, these children have abnormal mitochondria on electron microscopy and abnormal energy production. This gene also causes a more complex phenotype called

*Barth syndrome*, an X-linked cardioskeletal myopathy with cyclic neutropenia, 3-methylglutaconic aciduria, cardiolipin deficiency, short stature in youth, and cholesterol depletion (274a,329–331). Other genes have also been identified, including  $\alpha$ -dystrobrevin in left ventricular noncompaction associated with congenital heart disease (325a) and Z-disk-associated PDZ domain protein (ZASP; (332)). These genes encode cytoskeletal proteins and Z-disk-localized proteins. Other children with early presentation of dilated HCM have been found to have mitochondrial abnormalities as well, and this occurs in both sexes (266a).

Evaluation of these children should include urinalysis for organic acids, serum amino acids, acylcarnitine profile, and skeletal muscle biopsy for microscopy, electron microscopy, and electron transport chain analysis (319).

**51.6.2.1 Management.** Therapy includes  $\beta$ -blockers in patients with HCM and hypercontractile function, with or without obstruction. In metabolic mitochondrial disorders, the metabolic derangement should be treated. Carnitine, coenzyme Q10, riboflavin, thiamine, and other vitamins are useful in some cases. In cases in which ventricular dysfunction occurs, anticongestive measures are necessary. Dysrhythmias are treated with medical therapy.

### 51.6.3 Dilated Cardiomyopathy

**51.6.3.1 Clinical Features.** DCM is characterized by increased ventricular chamber size, decreased wall thickness, and impaired systolic ventricular function (333). Secondary diastolic dysfunction may also occur. Owing to the left ventricular dilation, the mitral ring stretches and the development of mitral regurgitation is common. When mitral regurgitation is significant, left atrial enlargement occurs and the development of pulmonary hypertension may occur. The most common clinical presentation is that of congestive heart failure (CHF), with resting tachycardia (probably due to increased sympathetic tone), dyspnea due to pulmonary edema, hepatomegaly, and poor perfusion due to low cardiac output (334–336). Syncope and sudden death may occur, and in many of these cases, VT/VF is the cause (238a,337–341). Many patients may have pericardial and/or pleural effusion as well. In addition to the ventricular tachydysrhythmias, supraventricular tachycardia (SVT) can occur. In some patients, conduction abnormalities are prominent.

**51.6.3.2 Genetics.** The prevalence of idiopathic DCM has been estimated to be approximately 40 cases per 100,000 (342–344). Familial DCM (FDCM) is estimated to account for 30–40% of patients with idiopathic DCM. Inheritance of FDCM is usually autosomal dominant, but X-linked, mitochondrial, and autosomal-recessive DCM also occurs. Genetic heterogeneity has been found for the autosomal-dominant form of FDCM. The first autosomal-dominant gene was identified by our

**FIGURE 51-16** Echocardiogram of left ventricular noncompaction. Note the deep endomyocardial trabeculations in the left ventricle (LV). AO, aorta; RV, right ventricle.

group on chromosome 1q32 (345). Five other chromosomal loci have been identified by us and by others, on chromosomes 10q21–23 (346), 5q33 (347), 9q13 (348), 15q14 (302), and 2q31 (349) (Table 51-3). Four additional chromosomal loci have been mapped to 1p1–1q1 (350), 1q11–1q21 (351), 3p22–25 (352), and 6q23 (353), in families having DCM in association with conduction defects; also notable is that one family linked to chromosome 6q23 has associated limb-girdle muscular dystrophy (LGMD) as well (353), while two other families had sensorineural deafness (354). In the families with conduction disease, transient dysrhythmias, which present in the second or third decade, become sustained and common place by the third or fourth decade (355). The abnormal rhythms included second- or third-degree AV block, AF, and marked bradycardia, commonly requiring a pacemaker. DCM usually developed in the fourth or fifth decade, generally out of proportion to the severity of the rhythm disturbance. Sudden death commonly occurred in the late stages of the disease. On autopsy, marked right and left ventricular dilation, interstitial fibrosis, myocyte degeneration characterized by cytoplasmic vacuolization, and AV nodal cell replacement by fibrous tissue were noted. The gene for the chromosome 1p–1q-linked disorder was shown to be lamin A/C (356), the same gene that causes autosomal-dominant EDMD (357). The other genes have remained elusive (Table 51-3). In the pure forms of FDCM, the genes identified generally encode proteins of the cytoskeleton, sarcomere, or sarcomere–sarcolemma link. The first three genes identified included  $\alpha$ -actin (15q14; (302)), desmin (2q31; (358)), and  $\delta$ -sarcoglycan (5q33; (347)) (Table 51-3). In addition to forming portions of the thin filament of the sarcomere, which is essential to the generation of force,  $\alpha$ -actin is also an important cytoskeletal protein involved in structural integrity and the transmission of force. Mutations in actin responsible for FDCM are located in the domain that is immobilized and attached to the Z-band or intercalated disk and involved with transmitting force. In contrast, it has also been shown that mutations in the actin domain affecting the myosin cross-bridges and the generation of force (sarcomere) give rise to familial HCM (265). Desmin is the specific intermediate filament for muscle and an essential cytoskeletal protein for maintaining cardiac structure and for the transmission of force and other signals to the cytoplasm and the nucleus of the cell. Desmin stretches from its attachment to the sarcomere Z-band to the nuclear membrane and other organelles (359). Mutations in desmin have been shown to be associated with cardiac and skeletal abnormalities (360). A missense mutation (Ile451Met) was found to be responsible for DCM in a family without any skeletal or smooth muscle abnormalities. Mutations leading to combined skeletal and cardiac abnormalities have all been in the rod region of desmin. In contrast, the Ile451Met mutation responsible for the restricted cardiac phenotype of

DCM encodes for the tail domain of human desmin, located in codon 451 with cytosine substituting for guanine. This would suggest a possible unique cardiac function for the domain in this region. Elimination of the desmin gene in a knockout mouse was associated with a phenotype of DCM exhibiting impaired cardiac function and myocyte necrosis.

Several new genes have been identified since 2000. Other cytoskeletal genes, such as metavinculin (352a) and  $\beta$ -sarcoglycan (361), were identified, along with those of the Z-disk, including  $\alpha$ -actinin-2 (85a), muscle LIM protein (MLP) (85a,362), the ZASP gene (332), and titin (352a). In addition, other sarcomeric proteins known to cause FHCM, such as  $\beta$ -MyHC (160a), cTnT (160a,363),  $\alpha$ -TM (352a), and MyBP-C (328a), have also been shown to cause DCM. A calcium homeostasis gene, phospholamban, was also shown to cause DCM when mutated. In all the cases described, irrespective of the gene, ventricular arrhythmias were prominent clinical features of the affected subject.

It is of note that the genes identified to cause DCM have also been shown to be associated with musculo-skeletal disorders. For instance, Duchenne and Becker muscular dystrophies (DMD and BMD) are due to dystrophin mutations,  $\beta$ - and  $\delta$ -sarcoglycan cause LGMD, lamin A/C causes EDMD, and desmin causes myofibrillar myopathy (364–367). Therefore, these cytoskeletal proteins appear to cause cardiac and skeletal muscle disease. There is, thus, a strong suggestion that FDCM may be a disease of the cytoskeletal proteins and the link with the sarcomere (368,369), analogous to HCM being a disease of the sarcomere (267) and LQTS and Brugada syndrome being an ion channelopathy (19,370). This has been termed the final common pathway hypothesis by Towbin (368,369) (Figure 51-17), and the concept has been reiterated by Katz (371).

**FIGURE 51-17** Final common pathway hypothesis. The concept developed here is that phenotypes result from mutations in genes encoding specific subtypes of proteins or cascade pathways that affect the function of these targets. For instance, hypertrophic heart disease results from mutations in sarcomeric proteins or in cascade pathways affecting these target proteins. Similarly, ventricular arrhythmias and dilated, dysfunctional hearts are caused by abnormalities of ion channels and cytoskeletal/sarcolemmal proteins, respectively, or cascade pathways involved in the function of these target proteins.

### 51.6.4 X-Linked DCM

**51.6.4.1 Clinical Features.** Berko and Swift (372) reported a five-generation kindred with DCM, X-linked inheritance, and no clinical evidence of skeletal myopathy. Males presented in their teens or early 1920s with clinical evidence of mitral regurgitation and an echocardiographic diagnosis of DCM. Episodes of VT were noted in several patients. The males progressed rapidly (within 1 or 2 years) to death or cardiac transplantation. Manifesting female carriers developed mild cardiomyopathy in the fourth or fifth decade and progressed slowly. Right ventricular endomyocardial biopsy revealed minimal interstitial fibrosis, while postmortem evaluation showed marked dilation, widespread patchy fibrosis (worst in the posterior wall), and normal mitochondria on electron microscopy. There were no pathognomonic findings differentiating this cardiomyopathy from other dilated forms, except for the apparent X-linked inheritance and elevation of the muscle isoform of creatine kinase (CK-MM) in the serum of affected males and female carriers.

**51.6.4.2 Genetics.** Towbin et al. (373) demonstrated linkage of X-linked dilated cardiomyopathy (XLCM) to the dystrophin (Table 51-4) locus at Xp21 (i.e. the gene responsible for DMD and BMD) in the family described previously, as well as in a second family. Evaluation of the protein defect in XLCM showed absence (or low abundance) of the N-terminal and rod portion of the dystrophin protein, while skeletal muscle total protein was normal (373). The 156 kDa dystrophin-associated glycoprotein (known as  $\alpha$ -dystroglycan) (373,374), a membrane-bound constituent of the dystrophin-associated glycoprotein complex, was decreased in abundance in cardiac tissue as well, and it was suggested that the entire dystrophin-associated glycoprotein complex

was involved (374) (Figure 51-18). This was later confirmed by others (202a,375–379). Diverse mutations leading to XLCM have been shown by Towbin and Ortiz-Lopez (380), Yoshida et al. (381), Muntoni et al. (382), Milasin et al. (383), and Ortiz-Lopez et al. (384), with most mutations residing in the 5' portion of the gene. Franz et al. (377) reported on a mutation in exon 29, however. In all cases, it appears that the DCM occurs because of mechanical destabilization of the muscle membrane. Other novel mutations in the 5' end of dystrophin, including a transposon (385) insertion and an Alu-rearrangement (376), were found to result in XLCM. Further, mutations in dystrophin have been shown to cause sporadic DCM (202a,202b). In addition, our group has shown that the N-terminal portion of dystrophin near the actin-binding domain is a “fragile site” in all forms of DCM, whether or not the dystrophin gene is mutated. Using immunohistochemistry and Western blots, all forms of DCM were shown by Vatta et al. (170a,170b,332) to have loss of N-terminal dystrophin, which may normalize during the process of reverse remodeling.

**51.6.4.3 Management.** Treatment of CHF and ventricular arrhythmias is necessary, and transplantation is common. Medical therapy includes an oral anticongestive regimen of digoxin, diuretic, and an angiotensin-converting enzyme inhibitor such as captopril or enalapril. Recently, the addition of a  $\beta$ -blocker such as metoprolol or carvedilol has become standard practice. Owing to the poor systolic function, the potential for the development of thrombi and embolic phenomena has led to the institution of therapy with aspirin or other medications. In some patients, inotropic support intravenously is needed; the usual approach includes use of renal-dose dopamine, milrinone, and possibly

other medications such as dobutamine, epinephrine, and norepinephrine. Ventricular assist devices or intra-aortic balloon pumps may be indicated in severe cases as a bridge to transplantation. Ventricular assist devices have recently been used as a bridge to recovery. We have shown that this approach normalizes dystrophin, fibrosis, and myocyte hypertrophy, enabling reverse remodeling (*170a,170b,332a*). Antiarrhythmic agents may be needed in some patients; ICD implantation is reserved for patients with life-threatening dysrhythmias.

### 51.6.5 Conduction Disease with DCM

**51.6.5.1 Clinical Features.** Families are described with variable conduction disease ranging from first-degree to second-degree AV block that occurs in the second or third decade of life and progresses to complete AV block over one or two decades (*355*). In these families, DCM occurs late in the course of the disease and is out of proportion to the conduction disease severity. Typically, these are autosomal-dominant transmitted disorders, and in some cases, skeletal myopathy is notable. A variety of genes have been identified thus far.

**51.6.5.2 Genetics.** In 2001–2010, several families have been studied using linkage analysis. The first gene for conduction disease with dilated cardiomyopathy (CDDC) was identified by Kass et al. (*350*) to be a chromosome 1p1–1q1-linked gene (*Table 51-3*). Subsequently, Olson and Keating mapped a second locus to 3p25–3p22 (*352*). In these families, no skeletal

myopathy was demonstrated. However, Messina et al. localized a gene to 6q23 in a family with skeletal myopathy (*353*), and Van der Kooi et al. (*351*) described another family, which they suggested as having LGMD (LGMD1B) with CDDC, and which they mapped to chromosome 1q11–1q21 (*271a,386*). The gene for the 1p1–1q1-linked CDDC was identified as lamin A/C (000a, (*66a,270a,356,387–389*)) (*Table 51-3*). This gene encodes two proteins that are members of the intermediate filament class of cytoskeletal proteins. The families identified had variable skeletal myopathy as well. The gene also causes autosomal-dominant EDMD, which has a similar phenotype although skeletal myopathy is central to the diagnosis in these patients (*357*). In CDDC, tachydysrhythmias including nonsustained VT, SVT, and AF occur in some of the affected patients, including young individuals (*390,391*).

Although the 3p25–p22-linked gene and 6q25-linked gene have not been identified, another group of similar patients have been shown to have mutations in the chromosome 2q-linked gene desmin, a myofibrillar protein that accumulates in the muscle fibers of affected patients (*358*). In skeletal and cardiac muscles, normal desmin encircles the Z-bands that hold together the actin filaments and help transmit tension along the myofibrils, protecting their structural integrity during repeated muscle contractions over time. Mutant desmin appears to cause fragility of the myofibrils and impair contraction. In mice lacking desmin, the same phenotype occurs but only later in life.

Most recently, Olson et al. (392) identified mutations in *SCN5A* in a family with DCM and AF as well as conduction abnormalities.

**51.6.5.3 Management.** The management of CDDC requires pacemaker implantation for symptomatic bradycardia. Signs and symptoms of CHF are treated with standard CHF therapy.

### 51.6.6 Arrhythmogenic Right Ventricular Dysplasia/Cardiomyopathy

ARVD/ARVC is characterized by fatty infiltration of the right ventricle, fibrosis, and ultimately thinning of the right ventricular wall (Figure 51-19) with chamber dilation (393–395). The residual myocardial fibers are often embedded in fibrous tissue, and this substrate is conducive to right ventricular reentrant arrhythmias. This is the most common cause of sudden cardiac death in the young in Italy (395) and is said to account for about 17% of sudden death in the young in the United States (393–396).

**51.6.6.1 Clinical Features.** The clinical presentation of ARVD/ARVC is highly variable and includes palpitations, syncope, right heart (or biventricular) failure, and sudden death (397). Some patients may be asymptomatic. Clinical manifestations are rare before puberty, with typical onset between 12 and 45 years of age, and sudden death is a common first symptom. It has been estimated that 3–4% of sudden deaths during sports (and 17% of all sudden deaths in young persons) occur because of this disorder, and it is well known that the dysrhythmias in this disease are most likely to occur during exercise.

ARVD/ARVC is extremely difficult to diagnose and, since there is no diagnostic standard, consensus criteria were developed (398) on the basis of structural, functional, and electrical manifestations. The structural changes most commonly noted include increased right ventricular chamber size, deep fissuring and trabeculation of the RVOT, localized akinetic or dyskinetic bulges

or outpouchings (particularly the infundibulum at the apex and posterior sub-tricuspid areas), and localized thinning of the right ventricular wall (399).

Morphologically, the most striking feature of ARVD/ARVC is fatty replacement of the epicardium and mid-myocardium of the right ventricular free wall (394,395). The endocardium is usually spared, as is the septum. As the disease progresses, the left ventricle may become involved, particularly the epicardial surface. Focal right ventricular thinning, especially in the infundibular region, in the diaphragmatic inferior wall, or at the apex, is typical. Histology demonstrates severe myocardial atrophy with residual myocytes interspersed with fibrofatty tissue. Evidence of patchy and acute inflammation with myocyte death and focal round cell infiltrate (lymphocytes) is present in approximately 70% of cases (400).

Clinically, the key feature of this disease is its propensity to tachydysrhythmias (397). During sinus rhythm, there are abnormalities of the QRS configuration that are due to slow conduction of electrical activity in the Purkinje system of the right ventricular wall, known as parietal block. In addition, there may be abnormalities of repolarization secondary to the underlying abnormal anatomy of the right ventricular free wall and chamber enlargement. These abnormalities include (i) prolongation of the QRS duration in the right precordial leads ( $V_1$ – $V_3$ ), representing alterations of conduction delay predominantly affecting the right ventricular free wall, the last portion of the heart to be depolarized; (ii) epsilon waves, small electrical potentials occurring immediately after the QRS complex and representing delayed right ventricular depolarization; (iii) presence of late potentials by signal-averaged ECG, also suggestive of delayed depolarization and typically associated with reduced right ventricular ejection fraction; (iv) T wave inversion beyond lead  $V_1$  in a patient older than 12 years of age, the extent of which correlates with the extent of right ventricular involvement; and (v) ventricular dysrhythmias (Figure 51-20). These are almost always of LBBB morphology as they arise from the right ventricular free wall (Figure 51-21). The propensity for dysrhythmias has been suggested to occur because of abnormalities of cardiac sympathetic innervation, with significant reduction of myocardial  $\beta$ -adrenergic receptor density (401). Owing to the high-risk features of ARVD/ARVC, it has been suggested that a registry be created (402).

**51.6.6.2 Genetics.** ARVD/ARVC is commonly inherited with a family history of disease being present in 30–50% of cases (397). With the exception of complex variants of the disease found in Naxos, Greece, and in Ecuador with a recessive mode of transmission (39a,403,404), the disease is transmitted in an autosomal-dominant pattern with various degrees of clinical expression. The autosomal-dominant form is genetically heterogeneous, with six genes for a pure form of ARVD/ARVC mapped to chromosomes 14q24.3 (ARVD1; (405)), 1q42–q43 (ARVD2; (406)), 14q12–q22 (ARVD3; (407)), 2q32.1–q32.3

**FIGURE 51-19** Gross anatomic findings in ARVD. Note the right ventricle free wall thinning with fatty replacement.

**FIGURE 51-20** Features of ARVD are seen in this electrocardiogram. Epsilon waves and T wave inversion in the lateral leads are seen.

**FIGURE 51-21** Left bundle-branch ventricular tachycardia in ARVD.

(ARVD4; (408)), 3p23 (ARVD5; 5), and 10p12–p14 (ARVD6; (363a)) (Table 51-3). To date, three genes for this disorder have been identified. The first gene, RyR2, is involved in calcium homeostasis. It has been identified as the gene for CPVT. The other genes, plakophilin-2 and desmoplakin, encode desmosomal proteins. A locus has also been identified for ARVD/ARVC associated with myofibrillar myopathy, a skeletal myopathy with axial and distal weakness, myopathic electromyographic

findings, and abnormal biopsies with myopathic changes; rimmed vacuoles; accumulation of desmin, dystrophin, and sarcoglycan; and myofibril disorganization. This gene was mapped to chromosome 10q22.3 (Table 51-3), but the gene has not yet been identified (409).

Two autosomal-recessive forms of ARVD/ARVC, Naxos disease and Carvajal syndrome, have been identified. The first of these, Naxos disease, was mapped to chromosome 17q21 (403). This complex disorder consists

of ARVD/ARVC associated with diffuse nonepidermolytic palmoplantar keratoderma and wooly hair, and has been identified on the Greek island of Naxos. The gene for this disorder was identified as plakoglobin (Table 51-3), a desmosomal protein (410). The second disease, Carvajal syndrome, has the same clinical phenotype as Naxos disease except left ventricular involvement occurs. This gene, localized to chromosome 6p21, has been identified as desmoplakin, another desmosomal protein. It is interesting that the autosomal-dominant myofibrillar myopathy/ARVC has desmin-like inclusions, suggesting that a similar gene product will be found to cause this disorder. As noted, the genes involved in the pure form of ARVD/ARVC also are involved in desmosomal function.

**51.6.6.3 Management.** Medical therapy consists of antiarrhythmic drugs to suppress ventricular arrhythmias, with sotalol (most common), amiodarone, flecainide, and propafenone reportedly used (399,411). Although sotalol appears to be effective in preventing recurrence of sustained VT, whether it is effective in preventing sudden death remains unknown. Catheter ablation of VT has been achieved in selected patients, but recurrences are not uncommon, probably because of the progressive nature of the disease. ICDs are currently recommended for patients who have had cardiac arrest or are deemed to be at high risk of syncope/sudden death or who have polymorphic VT (399). Owing to the fatty infiltrate, implantation (and function) of the ICD may be problematic.

## 51.6.7 Restrictive Cardiomyopathy

**51.6.7.1 Clinical Features.** Restrictive cardiomyopathy (RCM) is the least common of the four major categories of cardiomyopathy (412,413). It is a primary abnormality of diastolic function caused by derangement in the dynamics of ventricular filling, resulting in an increase in ventricular end-diastolic pressures and dilated atria (Figure 51-22). Systolic

function is usually preserved. Pulmonary hypertension commonly occurs (414). The diagnosis may be made by an ECG in which extreme P wave (atrial) voltage and width is notable and an echocardiogram with severe atrial dilation with normal ventricular size and function (Figure 51-23). Ischemia and ventricular tachydysrhythmias may occur as do atrial tachydysrhythmias and conduction abnormalities. Sudden death is common (371a,412,415–417). Secondary RCM can develop in the late stages of HCM (418); DCM; valvular, hypertensive, and ischemic heart disease; or specific heart muscle disease, such as amyloidosis (419,420). The most common cause of secondary restrictive cardiomyopathy in adults is myocardial amyloid. Patients manifest exercise intolerance due to their inability to increase cardiac output by tachycardia without further compromising ventricular filling. Weakness and dyspnea are often prominent, and chest pain may also occur. At the end stage, the findings are those of cardiac failure with anasarca (414,421).

**51.6.7.2 Genetics.** Mutations in the transthyretin (TTR) gene (389a,422,423), which codes for the TTR serum protein, have been found to be associated with RCM (Table 51-3). This protein contains four subunits, each with 127 amino acids, encoded by four exons within a 7kb gene. Many TTR point mutations cause TTR to form amyloid, which occurs primarily in the heart, leading to heart failure.

Familial forms of RCM have also been seen. In these cases, autosomal-dominant and autosomal-recessive inheritance have been described. One such family was found to have mutations in the desmin gene (424) (Table 51-3), and mice have been created with desmin mutations that have a phenotype similar to the clinical condition (425,426). Another gene, troponin I, was identified in cases of RCM with and without associated LVH.

**51.6.7.3 Management.** In patients with CHF, anticongestive therapy is appropriate (412,414). However, most patients do not improve with any medical therapy and, because of the high risk of sudden death, transplantation may be the first-line therapy. The use of ICDs is controversial.

## 51.7 NEUROLOGIC DISORDERS ASSOCIATED WITH DYSRHYTHMIAS AND CONDUCTION DISEASE

Numerous atrial and ventricular dysrhythmias can be seen in certain familial neurologic diseases as can myocardial diseases (DCM, HCM, RCM). Generally, the most common rhythm disturbances associated with neurologic diseases are due to abnormalities of the cardiac conduction system. The following neurologic disorders are discussed: DMD, BMD, EDMD, LGMDs, congenital muscular dystrophies, myotonic dystrophy (DM), Friedreich ataxia, and mitochondrial myopathies.

**FIGURE 51-22** Restrictive cardiomyopathy. This echocardiogram identifies the diagnostic features: dilated atria with normal ventricular size, thickness, and systolic function. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

### 51.7.1 Duchenne Muscular Dystrophy

**51.7.1.1 Clinical Features.** DMD is an X-linked disorder characterized by the early onset of progressive, generalized muscle weakness and “pseudohypertrophy” of certain muscle groups (427,428). The incidence of DMD is estimated to be one in 3300 live male births, with little ethnic variation, and the calculated mutation rate of  $10^4$  is an order of magnitude higher than for most other genetic diseases. Approximately 35% of cases arise by spontaneous mutation, with the remaining two-thirds occurring by inheritance of the disease-causing gene from the carrier mother. Female carriers of DMD are usually asymptomatic but occasionally have a slowly progressive myopathy of moderate severity (429,430). This “manifesting female carrier” state occurs in approximately 8% of carriers and is thought to occur because of random X-inactivation. Cardiomyopathy may be the first clinical manifestation of female carriers (431). The disease may also be expressed in females with Turner syndrome having a single X chromosome and in females with X-autosome translocations that disrupt the *DMD* gene. In the latter case, the translocation not only disrupts the *DMD* gene but also causes the nonrandom inactivation of the normal allele on the other X chromosome, resulting in the expression of the disease phenotype.

Although evidence of skeletal muscle disease in boys with DMD is evident in the neonatal period, as seen by high serum muscle enzymes (particularly CK-MM), clinical disease is not. There may be a mild developmental delay, with walking later than expected, but weakness

is usually not appreciated until at least 2 or 3 years of age (428). Early symptoms reported by parents include difficulty in running or climbing stairs, frequent falling, and enlargement of calf muscles. Pelvic girdle weakness is more obvious than shoulder girdle weakness in the early stages. The gait becomes lordotic and waddling, and the child usually walks with the heels raised slightly off the ground (i.e. toe walking). As pelvic girdle weakness increases, the child has increasing difficulty rising from a seated position. In order to rise from the floor to a standing position, the child must brace the arms against the front of the thigh and climb up the legs, the so-called *Gower sign*. Muscle pseudohypertrophy usually appears by 5–6 years of age, with muscle enlargement most commonly occurring in the calf muscles; the quadriceps, infraspinatus, deltoid, and gluteal muscles may also be involved, however. The upper and lower extremities become progressively weaker with age, and joint contractures may appear because of uneven weakness of agonist and antagonist muscles. Contractures of the hip flexors, iliotibial bands, and heel cords develop in 70% of patients between 6 and 10 years of age. Most patients are wheelchair-bound by the end of the first decade of life. After ambulation is lost, fixed contractures occur and paraspinal muscle weakness leads to progressive kyphoscoliosis. Significant weakness of the respiratory muscles occurs early in the second decade and is a common cause of demise.

While most cases of DMD can be recognized on the basis of the patient’s history and clinical signs alone, laboratory evaluation is important to confirm the diagnosis (427). As previously noted, extremely high levels of

**FIGURE 51-23** Restrictive cardiomyopathy. Batrial enlargement (tall, wide P waves) and left ventricular hypertrophy (large-voltage QRS in  $V_6$ ) are noted along with ST segment depression in the inferior lateral leads, which is particularly noticeable in the rhythm strip.

CK-MM are found in the early stages of disease, as early as birth, and precede evidence of clinical involvement. Other muscle enzymes, including aldolase, aspartate aminotransferase, lactate dehydrogenase, and pyruvate kinase, are also grossly elevated. In the end stages of the disease, enzyme levels fall but do not reach normal values. Electromyographic examination may also be useful, demonstrating the characteristic features of a myopathy (432). Insertional activity is normal or increased initially, but decreases in the advanced stages of the disease, when fibrosis replaces muscle fibers. Fibrillation potentials and positive sharp waves occur in the early stages of the disease due to the splitting of muscle fibers. The motor unit potentials are small and polyphasic, and an early recruitment pattern with minimal effort is present. Mild intellectual impairment is common in patients with DMD. The retardation is present at an early age, is nonprogressive, and does not correlate well with the stage of the disease. Approximately one-third of patients have IQs less than 75, characterized primarily by impaired verbal ability.

The heart is commonly involved in DMD, with ECG abnormalities and DCM being most typical (427,433,434). Cardiac symptoms, however, are reportedly unusual before the terminal stages of the disease. CHF tends to occur (435). A midsystolic click and late systolic murmur associated with mitral valve prolapse (MVP) are also common. In addition, an  $S_3$  or  $S_4$  gallop, sinus tachycardia, and a mitral regurgitation murmur are usually heard along with cardiomegaly and increased pulmonary vascular markings on chest radiograph; at this stage, bilateral diaphragmatic elevations may be seen because of diaphragmatic dystrophy. Unlike the late-onset findings of DCM, the ECG is abnormal early in the course of DMD, with a tall R wave and an abnormally increased R/S ratio in the right precordial chest leads and a deep, narrow Q wave in leads I,  $aV_L$ ,  $V_5$ , and  $V_6$  (434). These abnormalities progress over time and are attributed to the finding that the greatest dystrophic myocardial changes are in the posterobasal and contiguous lateral left ventricular myocardium. In addition, P waves with negative terminal deflections in  $V_1$  exceeding 20 ms and 0.1 mV appear in 20–45% of patients and, in the absence of left atrial enlargement on echocardiogram, are attributed to an intrinsic disorder of left atrial or intra-atrial conduction. A short P–R interval may be seen in up to 50% of patients but is not thought to be due to a bypass tract as seen in WPW syndrome. Infranodal conduction abnormalities, however, may be seen in patients with DMD; these include complete or incomplete bundle-branch block and left anterior or posterior fascicular block. Atrial and ventricular premature beats and atrial flutter are seen in some patients.

Echocardiography reveals left ventricular dilation and dysfunction, with significantly reduced shortening fraction or ejection fraction, and left ventricular

hypokinesis of the posterobasal ventricular wall is identified (365,373,436). Doppler and color Doppler commonly demonstrate mitral regurgitation, secondary either to the DCM or to the associated MVP, which occurs secondary to papillary muscle dysfunction (437). In some patients, systolic function appears normal but diastolic dysfunction is present.

Histopathologic abnormalities of the heart and skeletal muscle are universal in patients with DMD, and those of skeletal muscle are widespread even in the early stages of disease (427,438). Typical findings are rounding of the muscle fibers, increased variability in fiber size, increased central nucleation, and fiber splitting. Necrotic and regenerating fibers are present along with large, round hyaline fibers. In the late stages, muscle may be virtually replaced by fat and fibrous tissue. In the heart, degenerative changes in muscle fibers and areas of fibrosis in the ventricles, atria, and conduction system occur, with most pronounced changes in the posterobasal region and adjacent lateral wall of the left ventricle. The underlying cause of cardiac disease is not currently known, but it is speculated that the gene defect in DMD leads to instability of the translated cytoskeletal protein, leading to weakening of the myocyte membrane and subsequent myocyte death due to mechanical stress (368,369,436).

**51.7.1.2 Genetics.** The dystrophin gene (Table 51-3), on the short arm of the X chromosome at Xp21 (427,439), may cause either low-level production of a nonfunctional protein or complete absence of dystrophin in the heart and skeletal muscle of affected patients when mutated. It is among the largest genes discovered thus far, comprising approximately 2.5 Mb and transcribing a 14 kb messenger RNA (mRNA) molecule (440–442). This cytoskeletal protein-encoding gene is normally expressed in striated and smooth muscle, as well as in brain. In muscle tissue, the dystrophin protein has been localized to the cytoplasmic surface of the sarcolemma and is associated with several integral membrane glycoproteins (443). This glycoprotein–dystrophin complex, which involves the sarcoglycans, dystroglycan, syntrophins, and dystrobrevins, connects dystrophin to the sarcolemma and links to the extracellular matrix (Figure 51-18); it may be involved in the regulation of intracellular calcium, which in dystrophin-deficient muscle is increased along with increased calcium channel transport (443–446).

The diagnostic approaches to DMD have changed dramatically in 2001–2010. Previously, serum CK-MM level and muscle biopsy were the standard approaches. Today, DMD is diagnosed primarily by molecular analysis (447), which is rapid and accurate and may predict clinical course. Most commonly, dystrophin mutations that cause a frameshift (441,448,449) of the nucleotide sequence result in the severe form of muscular dystrophy, DMD.

**51.7.1.3 Management.** Management of the CHF associated with the DCM seen in DMD is identical to that

used for patients with other causes of heart failure and dysrhythmias. Pacing is not usually necessary.

### 51.7.2 Becker Muscular Dystrophy

**51.7.2.1 Clinical Features.** BMD is an X-linked disorder that differs in both severity and time of onset from DMD (427,432), despite being due to allelic mutations in dystrophin, the gene responsible for DMD. BMD appears later and progresses more slowly than DMD, so that survival to middle age is seen. The pattern of muscle weakness, however, is identical to that in DMD, with early involvement of the pelvic girdle and proximal lower extremities (427). The initial signs of weakness usually appear during the second decade, but may occur as late as the third decade. The weakness gradually progresses, with the upper extremities becoming involved after 5–10 years. Patients generally remain ambulatory until their mid-30s. Similar to DMD, muscle hypertrophy is common; intellectual impairment, however, is less common and less severe. As in DMD, life expectancy is also reduced in BMD, with only 50% of patients surviving to 40 years of age.

Cardiac involvement may be seen in adolescence and ultimately affects 80% of patients (450). As in DMD, DCM and cardiac failure are the usual abnormalities encountered and are often the ultimate cause of death. Conduction abnormalities manifesting as fascicular block or complete heart block are also seen. As in DMD, muscle enzyme activity is markedly elevated in BMD, and preclinical cases may be detected by elevated CK-MM. Electromyographic examination shows a “myopathic” pattern with small, polyphasic motor units and early recruitment of motor units. The histology of BMD is similar to that of other forms of muscular dystrophy. In contrast to DMD, hyaline fibers are rarely seen. Electrocardiographic changes are similar to those seen in DMD. Other ECG abnormalities encountered include LAD, RBBB, LBBB, and complete heart block. The echocardiogram may demonstrate the features of DCM.

**51.7.2.2 Genetics and Management.** BMD is also due to mutations within the dystrophin gene; that is, it is allelic with DMD (Table 51-3). As is the case with DMD, more than 30% of patients with BMD have no family history of the disease, an indication that they represent spontaneous mutations. The phenotypic difference between DMD and BMD patients has been speculated to be due to frameshift mutations leading to more severe disease (DMD) while out-of-frame mutations cause less severe (BMD) disease (448,449,451,452). The frameshift hypothesis explains more than 90% of the cases of DMD versus BMD. The cardiac abnormalities in BMD, as with those described for DMD, require further study (381). However, cardiomyopathy is quite common (381,430,435,436,450,453,454). The treatment of CHF

and arrhythmias is similar to other patients with these signs and symptoms.

Animal models have been created during the past several years that help to characterize the roles of dystrophin and the associated complexes. Loss-of-function mutations of dystrophin lead to a DMD or BMD phenotype, while utrophin-deficient mice have defects in the postsynaptic membrane folds at the neuromuscular junction. Mice lacking both dystrophin and utrophin display a severe muscular dystrophy with premature death (455–458). Sarcoglycan-deficient mice also demonstrate severe muscular dystrophy but, in addition, severe HCM and/or DCM have/has been seen (459–461). This has recently been supported by the identification of  $\delta$ -sarcoglycan mutations in humans with FDCM by our laboratory (347).

Various methods evaluating the possibility of gene therapy for dystrophinopathies have been reported over the past several years in mice with varying degrees of success. Mini-gene and stem-cell transplantation have both been considered promising using dystrophin and utrophin (386a,462–467).

### 51.7.3 Limb-Girdle Muscular Dystrophy

**51.7.3.1 Clinical Features.** LGMDs are a heterogeneous group of muscle disorders first described in 1954 and characterized by predominant weakness and wasting of muscles of the pelvic and shoulder girdle (468). Facial and extraocular muscles are usually spared. There is a broad clinical heterogeneity, and this is paralleled by genetic heterogeneity (469,470). The heart is affected in several forms of LGMD, including cardiomyopathy (dilated and hypertrophic) and conduction system abnormalities (365,427,443). Onset can occur at any age, in childhood or adulthood, but usually has its onset after walking has started. Autosomal-dominant and autosomal-recessive forms of LGMD have been described, with the age of onset generally earlier in the autosomal-recessive forms (469).

**51.7.3.2 Genetics.** A classification scheme for the LGMDs has been devised that depends on the pattern of inheritance (469). The autosomal-dominant forms of LGMD are designated LGMD1 (LGMD1A–1D), whereas the autosomal-recessive forms are designated LGMD2 (LGMD2A–2G). This classification scheme is based on the inheritance and the specific gene causing the disorder (Table 51-4). The majority of recessive LGMDs are due to mutations in the dystrophin-associated protein subcomplex sarcoglycan (471–479), with LGMD2C, 2D, 2E, and 2F being caused by  $\alpha$ - (480),  $\beta$ -,  $\gamma$ -, and  $\delta$ -sarcoglycan, respectively (i.e. sarcoglycanopathies) (Table 51-3). Although quite variable in severity, these LGMDs tend to have a course that is often reminiscent of DMD in its severity. In all cases, cardiac disease can occur (365) and includes conduction system disease and cardiomyopathy (HCM and/or DCM). The other recessive

forms of LGMD are caused by mutations in calpain-3 (481,482), a muscle-specific calcium-dependent protease (LGMD2A), resulting in a somewhat milder course than the sarcoglycanopathies. Recently, LGMD2B was characterized as being caused by mutations in dysferlin (483,484), a novel muscle protein of uncertain function, and LGMD2G was found to be caused by mutations in the sarcomeric protein telethonin, a protein localized to the Z-disk of muscle (485). In this form, cardiomyopathy occurs (Table 51-4).

The autosomal-dominant forms of LGMD have been more difficult to identify thus far (486,487). The only gene identified to date is caveolin-3 (488), which causes LGMD1D. In LGMD1B, and 1C, and 1D, cardiac dysrhythmias can become evident concomitant with the initial stages of muscular weakness (Table 51-3). Cardiomyopathy is found as well (351,353) (Table 51-4).

Multiple animal models of the LGMDs have been reported, with most having cardiac disease. Cardiomyopathy and premature death consistently occur. In addition to the murine models, a naturally occurring hamster model with associated cardiomyopathy has been well described and occurs due to  $\delta$ -sarcoglycan mutation (366,460,461,489–491).

## 51.7.4 Emery–Dreifuss Muscular Dystrophy

**51.7.4.1 Clinical Features.** EDMD is a relatively rare disorder characterized by weakness in the humeroperoneal distribution, early joint contractures, and DCM (311a,492–495), with X-linked (493) inheritance. Occasionally, autosomal-dominant (496,497) or autosomal-recessive (498,499) inheritance is seen. The onset of disease in these patients occurs between 2 and 10 years of age, with weakness initially noted in the shoulder girdles and upper extremities. Contractures of the elbows and posterior cervical muscles appear early. The disease is slowly progressive, with involvement of the distal leg musculature following that of the upper extremities; contractures of the knees and ankles follow contractures of the elbows. Unlike DMD and BMD, muscle pseudohypertrophy does not occur (492). The disease evolves slowly and usually stabilizes in the third decade, with most patients remaining ambulatory. DCM is a common occurrence, but the severity of disease varies from family to family (492,493). Varying degrees of AV block are common, and atrial standstill may occur. These electrical abnormalities may lead to episodes of syncope, transient ischemic attacks, stroke, and sudden death. A pacemaker is commonly required. AF has also been observed. As in DMD and BMD, muscle enzyme activity is elevated, albeit to a lesser extent. Skeletal muscle biopsy histopathologic findings are similar to those associated with other forms of muscular dystrophy. Type I fiber atrophy has been described in some cases.

**51.7.4.2 Genetics.** The gene responsible for X-linked EDMD was localized to Xq28 (500) before being cloned

(501) (Table 51-3). The gene, called emerin (or STA), was shown to have an open reading frame of 762 nucleotides that encodes a serine-rich 254-amino-acid protein with probable mechanical/structural function (501). Emerin mRNA shows ubiquitous tissue distribution, with the highest expression in skeletal and cardiac muscles. The complementary DNA sequence of emerin predicts a tail-anchor membrane protein with amino acid sequence similar to thymopoietins, a group of nuclear lamina-associated proteins (502). Nagano et al. (331a) and Manilal et al. (503) both showed that emerin is a 34kDa nuclear membrane protein in skeletal and cardiac muscle that is absent in EDMD. Emerin belongs to a family of type II integral membrane proteins that are anchored to the inner nuclear membrane via hydrophilic tails, with the remainder of the molecule projecting into the nucleoplasm (503,504). This family includes lamins, lamin receptor, and thymopoietin  $\beta$ . Emerin is also found at intercalated disks and is thought to result in conduction defects due to this localization (505) and its interactions with desmosomes and fascial adherans.

The autosomal-dominant form of EDMD was initially mapped to chromosome 1 (1q11–q23) and the gene was identified as lamin A/C (357) (Table 51-3). The encoded protein is also a nuclear lamina-associated protein and is expressed in myocytes and adipocytes. In the nuclear inner membrane, this protein has a distribution that mirrors that of emerin (506). The phenotypic spectrum of this gene appears to be broad when mutated. In some cases, only a DCM phenotype with conduction disease (356,387) occurs (in the absence of clinical skeletal muscle disease), while in other cases, familial Dunnigan-type lipodystrophy (507) occurs. It is believed that the nuclear membrane either plays a critical communication role or a structural role through interactions with cytoskeletal proteins (506,508).

**51.7.4.3 Management.** The DCM associated with EDMD is treated with the usual anticongestive medical regimen, and conduction disease typically requires a pacemaker.

## 51.7.5 Myotonic Dystrophy

The most common adult-onset muscular dystrophy in humans, DM, is a progressive, multisystem disorder that manifests as a highly pathologic phenotype of the skeletal muscle, smooth muscle, brain, lens, testicular function, glucose metabolism, and heart (509,510). The variable phenotype in DM is further expanded by clinical “anticipation,” a phenomenon in which the severity of symptoms increases while the age of disease onset decreases with each successive generation within a family (511). Thus, the spectrum of DM symptoms can vary from mild, where only cataracts develops late in life, to a severe congenital form associated with skeletal muscle hypotonia, often resulting in respiratory arrest and death. An intermediate adult-onset form also occurs,

which manifests with one or more characteristic feature of DM, including myotonia (an abnormal muscle membrane depolarization resulting in abnormally delayed muscle relaxation time after strong muscle contraction), skeletal muscle weakness and wasting, cardiac conduction system disease with or without DCM, cataracts, endocrine dysfunction, frontal balding, epitheliomas, and mental retardation (Table 51-5).

**51.7.5.1 Clinical Features.** Although a range of skeletal muscles can be affected in DM, fast-twitch muscles are usually more severely affected than slow-twitch muscles. During the course of the disease, it is common to find early involvement of facial and neck muscles, with later involvement of extensor forearm and anterior tibial muscles, and muscles of the hands and feet. The heart is affected in approximately 80% of patients (512,513), and sudden death occurs with a high incidence (15–30%). Cardiac abnormalities are primarily conduction disorders, which occur in 45–80% of DM patients, and the increased incidence of sudden cardiac death occurs from either complete AV block or ventricular dysrhythmias (514–516). Disorders of impulse formation in the sinus node also occur, and a significant number of patients exhibit sinus bradycardia (Table 51-5). The cardiac

conduction abnormalities typically have a gradual but predictable increase in severity, often progressing from intermittent to stable first-degree AV block followed by more serious intraventricular block, including bundle-branch blocks and ultimately progressive AV block to complete heart block (514,517,518). Ventricular dysrhythmias, including VT, may also occur.

A rough correlation exists between the severity of the neuromuscular disease and progression of the cardiac features. DM is occasionally associated with overt cardiac failure, with 28% of patients having systolic dysfunction (519). MVP is seen in 17–32% of patients as well (520,521). Similar to conduction abnormalities, echocardiographic abnormalities usually are more prevalent in older patients with severe neuromuscular symptoms.

**51.7.5.2 Genetics.** Myotonic dystrophy, because of its variable presentation, may be underdiagnosed, and therefore, only conservative estimates of incidence can be made. Currently, it is believed that the incidence is 4.5–5.5 per 100,000 live births (522). DM is inherited as an autosomal-dominant disorder but does demonstrate two unique non-Mendelian features. Both the sex and the position of the parent within the pedigree affect the severity of disease in the subsequent generation due to genetic anticipation (511). In addition, the adult-onset form is inherited more frequently through the father, while congenital DM is almost exclusively maternally inherited.

The gene responsible for DM was initially mapped (523) to the long arm of chromosome 19 (19q13.3), and subsequently, the *DM* gene was identified as myotonin protein kinase (524–526), a serine/threonine kinase (DMPK) (527) (Table 51-3). The causative mutations are CTG repeat sequence expansions in the 3'-untranslated region of DMPK, which cause alterations in the expansion of neighboring genes when large enough (528,529). The probability and amplitude of the expansion increases as a function of repeat tract length, and the severity of the disease correlates with length of the repeat sequence (530). Two distinct patterns of CTG expansion have been described. Small changes in repeat size appear to predominate at repeat tract lengths <150 bp (35 repeats) in length. Such changes in tract size are reflected in the range of repeat tracts observed in the normal population (5–35 repeats). Once a threshold of >50 repeats is reached, however, the pattern of instability appears to change dramatically, causing the frequency of large repeats (>200 repeats) to greatly increase. In congenital DM, enormous expansions occur, reaching values >10 kb.

It is currently believed that nuclear retention of mutant DMPK transcripts occur in the nuclei of DM fibroblasts and muscle, causing a decrease in the pool of translatable DMPK mRNA in the cytoplasm (531). Titration of CUG-BP (a novel CUG-binding protein believed to play a role in processing and/or transport of

**TABLE 51-5 Systemic Involvement in DM**

<b>Muscle</b>	
Skeletal muscle	Myotonia, weakness and dystrophy predominately of facial, neck, and distal limb muscles
Heart	Conduction disorders more prominent than overt cardiomyopathy (dilated). Conduction abnormalities include disorders of impulse formation (sinus bradycardia, prolonged SA node recovery time, SA node dysfunction); disorders of impulse conduction (AV block including primary through complete AV block; intraventricular conduction defects including fascicular block, bundle branch block); and dysrhythmias, including premature atrial beats, atrial fibrillation and flutter, premature ventricular beats, and VT.
Smooth muscle	Widespread involvement of pharynx, esophagus, colon, and uterus. Delayed relaxation and abnormal peristalsis.
<b>Central nervous system</b>	
Brain	Mental retardation, hypersomnolence
Eye	Cataracts, decreased vision independent of cataracts
<b>Endocrine</b>	
Testis	Gonadal atrophy
Metabolism	Abnormal carbohydrate metabolism
<b>Skeletal/Skin</b>	
Skeletal	Cranial and facial abnormalities, talipes
Skin	Premature balding, calcifying epithelioma
<b>Lungs</b>	
Respiration	Hypoventilation

AV, atrioventricular; SA, sinoatrial.

CUG-encoding mRNAs) by the mutant DMPK message could allow DMPK levels to drop below 50% of normal (532–534). Reddy et al. (535) developed a mouse model, in which DMPK is functionally inactivated (DMPK<sup>-/-</sup>) and showed that loss of DMPK results in late-onset skeletal myopathy characterized by 30–50% loss in muscle twitch and tetanic force development by 11 months of age. Ultrastructural changes included Z-line loss, mitochondrial and sarcoplasmic reticulum abnormalities, and loss of sarcomere organization, suggesting that impaired excitation–contraction coupling or contractile apparatus abnormalities underlie the progressive muscle weakness seen in DM. Although DMPK is clearly an important component of muscle, loss of its expression cannot explain the complete DM phenotype. Timchenko (534) has suggested that RNA CUG repeats play a significant role in the development of the full phenotype. Wang et al. (536) initially demonstrated that DMPK poly(A)<sup>+</sup> RNA is significantly reduced in muscle biopsies from DM patients although total RNA had normal DMPK transcript levels, and suggested that the repeat expansion caused abnormalities in RNA processing. Timchenko et al. (537) further suggested that CUG repeat-containing DMPK RNA could affect processing of other mRNAs, perhaps by sequestering specific RNA-binding proteins, and thereby causing tissue-specific abnormalities.

Genetic heterogeneity exists for DM as well. Ranum et al. (538) identified a second locus for DM, called DM2, on chromosome 3q. Although the gene at this locus is not yet known, it is likely that DM2 could be associated with CTG repeats in a gene different from (but similar to) DMPK or with another type of triplet repeat expansion, and that RNA processing could modify the clinical features of this gene as well.

Finally, animal models have been created that mimic the clinical findings in humans (535,539–541). These animals continue to be studied in order to further unravel the molecular physiology responsible for this disorder.

**51.7.5.3 Management.** Management of DM involves the treatment of the skeletal myopathy with occupational and physical therapy and, when needed, use of a wheelchair. Cardiac abnormalities require pacemaker implantation for the conduction disorder and anticongestive therapy for patients with heart failure.

## 51.7.6 Friedreich Ataxia

**51.7.6.1 Clinical Features.** Friedreich ataxia is the most common of the hereditary spinal cerebellar degenerations, with an incidence of 1 in 50,000 and a carrier frequency of 1 in 110 (542). This autosomal-recessive form of spinocerebellar degeneration is characterized by progressive limb ataxia, loss of deep tendon reflexes, sensory abnormalities, and musculoskeletal deformities. The symptoms of Friedreich ataxia usually appear insidiously during childhood or early adolescence. Progressive weakness of the upper

and lower extremities gradually becomes obvious. Gait difficulties are often the first symptom, which progress slowly followed by unsteadiness in the arms and hands. Difficulty in writing and handling eating utensils subsequently becomes apparent.

Cardiac involvement (542) occurs in 50–90% of patients, and the most common abnormality is HCM; DCM occurs rarely. Thus, the most common cardiac symptoms relate to cardiac failure and dysrhythmias (543–545). Left ventricular outflow tract obstruction due to asymmetrical septal hypertrophy may be evident, and approximately 50% of patients die of cardiac disease. Patients are followed for development of dysrhythmias and the signs and symptoms of cardiac failure.

Involvement of the heart is readily detected by ECG and echocardiography (544). The ECG abnormalities are found in 90% of patients and include repolarization abnormalities manifesting as inverted or biphasic T waves in the inferior limb leads and left precordial leads, a short P–R interval, left and right ventricular hypertrophy, and left and right axis deviation. Premature atrial contractions, atrial flutter/fibrillation, and premature ventricular contractions are common (543,544). Echocardiography detects cardiac involvement in 60–100% of patients, with the most common finding being concentric hypertrophy, but asymmetrical septal hypertrophy accompanied by systolic anterior motion of the mitral valve is also common. Left ventricular chamber diameter may be normal or decreased, and ejection fraction or shortening fraction is usually normal or depressed, although DCM (left ventricular dilation and reduced contractility) is seen occasionally. There is no specific treatment for the cardiac manifestations except symptomatic treatment if cardiac failure ensues.

**51.7.6.2 Genetics.** Friedreich ataxia is inherited as an autosomal-recessive disorder, and parental consanguinity has been noted in some cases. The gene was initially mapped to chromosome 9q13–31.1 (546) and, in 1996, the gene was identified (547). This gene is 40 kb, contains five exons, has a 1.3 kb transcript, and encodes a 210-amino-acid protein called frataxin (Table 51-3). The highest level of expression is within the heart, while intermediate levels are seen in liver, skeletal muscle, and pancreas; minimal levels are identified in other tissues, including the brain. Although a few affected patients were found to have a point mutation of frataxin, the majority (~95%) are homozygous for an unstable GAA trinucleotide expansion in the first intron (547). The remaining patients are compound heterozygotes for the expansion. In patients homozygous for the expansion, there is a correlation between the number of GAA repeats on the smaller allele, age of onset, disease progression, and cardiomyopathy (223a,542,548–550), confirming that the expansion is the primary cause of disease. The expansion results in severely reduced levels of mature frataxin mRNA (547). Using immunocytofluorescence and immunocytoelectron microscopic evaluation,

Campuzano et al. (551) demonstrated that frataxin is localized to the mitochondria, associated with the mitochondrial membranes and crests. They suggested that reduction in frataxin results in oxidative damage. Subsequently, Rotig et al. (552) suggested that frataxin regulates mitochondrial iron transport and that deficiency of iron–sulfur cluster-containing subunits of mitochondrial respiratory complexes I and II and the iron–sulfur protein aconitase occurs. Hence, it appears that Friedreich ataxia is a mitochondrial disorder (362a,553). As these patients have HCM, diabetes, ataxia, and apparent free radical toxicity, the mitochondrial basis of this disorder clarifies the clinical features.

**51.7.6.3 Management.** The management of this disorder is symptomatic. The HCM is typically treated with a  $\beta$ -blocker or calcium-channel blocker, while the other symptoms are increasingly treated with mitochondria-based therapy, such as vitamins and free-radical-reducing agents (i.e. coenzyme Q10, ibedenone, riboflavin, thiamine, vitamin K).

## 51.7.7 Mitochondrial Disorders

Mitochondria are intracellular organelles that participate in several metabolic pathways, including ATP synthesis by oxidative phosphorylation (333,554,555). Mitochondria are unique organelles because they contain a genome that encodes some of the polypeptides in the oxidative phosphorylation pathway and all the transfer RNA (tRNA) and ribosomal RNA (rRNA). Nuclear genes encode the remaining mitochondrial proteins. Mitochondria self-replicate and are derived from oocytes. Thus, mutations in the mitochondrial genome are maternally inherited (554).

**51.7.7.1 Clinical Features.** Cardiac abnormalities are common in mitochondrial disorders and include conduction defects, HCM, DCM, and combined HCM/DCM, which may in part represent progression from the hypertrophic form (556,557). Leber hereditary optic neuropathy, a disorder in which there is a loss of central vision due to degeneration of the retinal ganglion cells and the optic nerve axons, commonly has associated WPW syndrome (404a,558–561). Other mitochondrial mutations are also associated with WPW syndrome; these include MELAS syndrome (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) (562,563) and MERRF (myoclonic epilepsy with ragged red fibers) syndrome (564,565). Another mitochondrial myopathy associated with cardiac disease is Kearns–Sayre syndrome, in which DCM and conduction disease are common findings (566).

**51.7.7.2 Genetics.** The human mitochondrial genome (567) is a small circular DNA molecule (Figure 51-24) that is maternally inherited. Mitochondrial DNA (mtDNA) encodes 13 of the 69 proteins required for oxidative metabolism, 22 tRNAs, and two rRNAs required for their translation. As mtDNA has much less redundancy than

**FIGURE 51-24** Mitochondrial DNA, a small circular molecule that encodes 13 of the 69 proteins required for oxidative metabolism, 22 tRNAs, and 2 rRNAs.

the nuclear genome (in which essentially identical information is received from both parents), and tRNAs and rRNAs are present in multiple copies, the mitochondrial genome is an excellent target for mutations giving rise to human disease (568,569). Mitochondria are dependent on nucleocytoplasmic mechanisms for most structural components, but do contribute vital peptides that are central to cellular respiration. The electron transport chain, which generates cellular ATP, is organized into complexes I–IV and the ATP synthase (complex V) (Figure 51-25). The 13 mtDNA genes that encode enzymes in the respiratory chain include seven complex I (569,570) subunits (ND1, 2, 3, 4L, 4, 5, and 6); one complex III subunit (cytochrome b); three complex IV subunits (COI, II, and III); and two complex V subunits (ATPase 6 and 8) (571–573). Each cell contains numerous mitochondria, and each mitochondrion contains multiple copies of mtDNA. In most mitochondrial disorders, patients carry a mix of mutant and normal mitochondria—a condition known as *heteroplasmy*, with the proportions varying from tissue to tissue and individual to individual within a pedigree, in a manner correlating with severity of phenotype.

Mitochondrial diseases often produce disturbances of brain and muscle function, and are usually evident during infancy or early childhood (555). Cardiac disease is most commonly seen with respiratory chain defects (556). Ragged red fibers are present in muscle biopsy specimens (574) almost invariably when the molecular defect involves mtDNA (564,575) (Table 51-3). These defects represent the genetics of ATP production. The diverse clinical syndromes associated with various respiratory chain complexes are thought to result from involvement of tissue-specific isoforms in some cases,

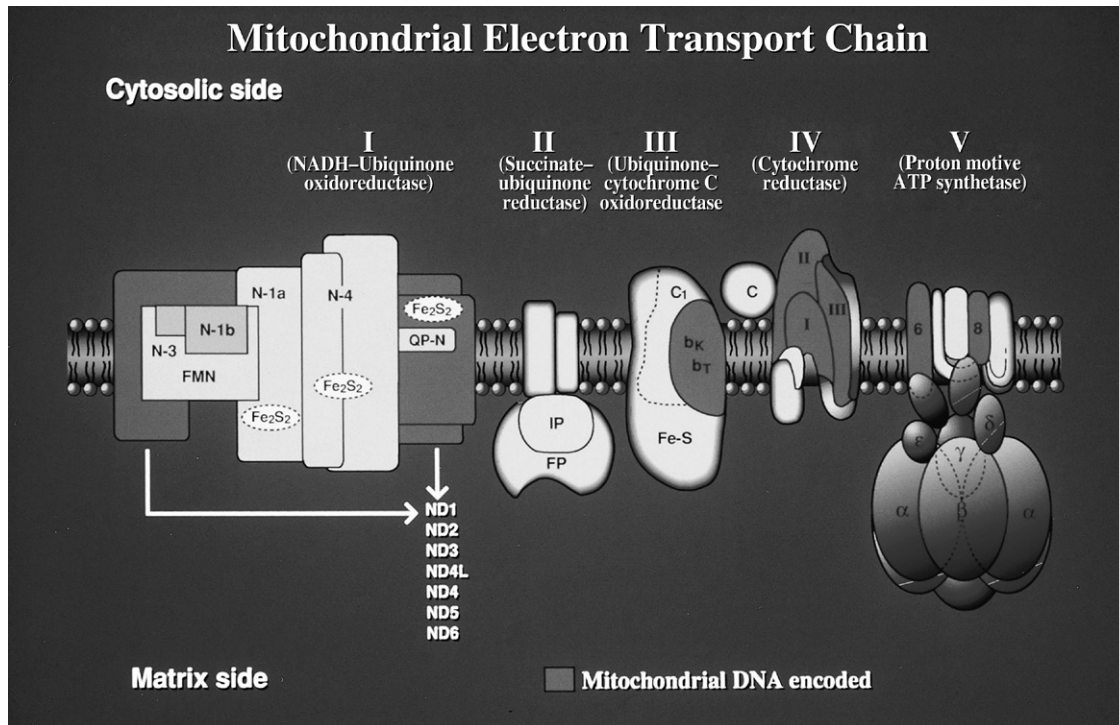

FIGURE 51-25 Oxidative phosphorylation pathway.

involvement of tissue-nonspecific (generalized) subunits in other cases, and the residual enzyme activity in affected tissues (575). The cardiac diseases seen associated with mitochondrial defects include both HCM and DCM (266a,556,569,576).

Mitochondrial gene mapping, in contrast to mapping of the nuclear genome, does not require genetic linkage. One simply has to show that the disease exhibits transmission through all mothers and no fathers in a sufficiently large family. Once this is established, the mitochondrial genome can be sequenced to identify the mutation, which must be shown to segregate with the disease, as there are many apparently harmless polymorphisms.

**51.7.7.3 Management.** Therapy for these disorders is generally symptom based. Conduction disturbance generally requires placement of a permanent pacemaker, and heart failure is treated with the usual therapy. In some patients,  $\beta$ -blockers may be useful. Hypertrophic heart disease is usually treated in a manner similar to that for other forms of HCM. Mitochondrial-based therapy may include coenzyme Q10, carnitine, or vitamins, but these therapeutic approaches typically do not alter the clinical course.

**51.7.7.4 Kearns-Sayre Syndrome.** This mitochondrial myopathy is characterized by ptosis, chronic progressive external ophthalmoplegia, abnormal retinal pigmentation, and cardiac conduction defects, as well as DCM (566). Hearing loss and limb weakness are frequently associated, as are endocrinopathies such as diabetes mellitus, hypoparathyroidism, and growth hormone deficiency. Approximately 20% of Kearns-Sayre syndrome patients have cardiac involvement and,

of these, the majority usually has conduction defects causing progressive heart block (388,577,578). These patients generally have large heterogenous deletions in the mitochondrial genome, of which tRNA<sup>leu(UUR)</sup>-3243 is most common.

Clinically, conduction abnormalities, bifascicular block, or progressive high-grade block may define the requirement for permanent pacemaker implantation. Symptomatic improvement using mitochondrial therapies may occasionally be seen with coenzyme Q10 therapy. The major function of coenzyme Q10 in mitochondria is to shuttle electrons from complexes I and II to complex III, while stabilizing the respiratory chain complexes. Vitamins such as phyloquinone (vitamin K<sub>1</sub>), menadione (vitamin K<sub>3</sub>), and ascorbic acid (vitamin C) have been used to donate electrons directly to cytochrome c. In addition, the endocrine abnormalities and heart failure should be treated in the usual way.

**51.7.7.5 LEOPARD Syndrome.** LEOPARD syndrome is an inherited disorder involving multiple organ systems. The acronym represents the abnormalities characteristic of this syndrome: multiple lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness. The conduction abnormalities include first-degree AV block, intraventricular conduction delay, and bundle-branch block (579,580). Progression to complete heart block is generally not seen. LEOPARD syndrome has been shown to be genetically heterogenous. A report of mapping to chromosome 17 with identification of the neurofibromin gene is documented (Table 51-3). In addition, mutations

in the *PTPN11* gene, which causes Noonan syndrome, have been shown to cause LEOPARD syndrome in a substantial percentage of patients (581). Therapy is supportive. HCM occurs in some patients with this disorder. A gene for LEOPARD syndrome was initially reported to map to chromosome 17, with subsequent identification of the neurofibromin gene. More recently, *PTPN11*, the gene identified for Noonan syndrome, has been shown to cause LEOPARD syndrome (157a,297a,582). Clearly, however, other currently unidentified genes for this disorder exist (583).

## 51.8 CONGENITAL HEART DISEASE AND DYSRHYTHMIAS OR CONDUCTION DISEASE

### 51.8.1 Atrial Septal Defects

**51.8.1.1 Clinical Features.** Atrial septal defects (ASDs) are common congenital heart malformations that account for more than 10% of isolated congenital heart defects (584). Ostium secundum ASD located in the region of the fossa ovalis is the most prevalent subtype and one thought to arise by malformation of the septum primum. This results in incomplete coverage of the fossa ovalis and shunting across the defect. Blood flow through the ASD depends on a variety of physiologic factors, including the ratio of left-sided (systemic) to right-sided (pulmonary) resistance, the ratio of left ventricular to right ventricular compliance, and defect size. Uncorrected ASDs can lead to increased pulmonary blood flow with secondary development of pulmonary artery hypertension, right ventricular hypertrophy, right-sided volume overload, heart failure, and death. In addition, ECG abnormalities are common and include variable degrees of AV block, atrial tachydysrhythmias (such as AF or atrial flutter), and abnormal ECG findings, including RBBB, right axis deviation, and right ventricular hypertrophy with strain (585,586).

**51.8.1.2 Genetics and Management.** Although most cases of ASD are sporadic, autosomal-dominant familial transmission has been well reported, particularly ASD associated with conduction system defects (584,587–589). Age-related penetrance has also been noted. Linkage analysis initially identified a locus on chromosome 5q35 (Table 51-3), and subsequently mutations in the transcription factor *Nkx2-5* were identified (590–592). Mutations in this gene were thought to destabilize the protein or disrupt the ability of *Nkx2-5* to target DNA binding. *Nkx2-5* defects appear to cause haploinsufficiency of a transcription factor meant to play a central role in cardiac morphogenesis, including the atrioventricular node. A second locus (5p) has been (was later) identified (Table 51-3), but the gene remains elusive (590). (Most recently, Robinson et al. (593) identified a locus on chromosome 3p25 in isolated cases and found mutations in the cell adhesion molecule *CRELD1*. These

authors also noted mutations in *CRELD1* in subjects with heterotaxy and ASD.)

Therapy of ASDs includes diuretic therapy when significant left-to-right shunting occurs. In patients with conduction disease, pacemakers may play a role.

### 51.8.2 Holt–Oram Syndrome

Da Vinci was the first to recognize that communication between right- and left-sided cardiac chambers resulted from defects in the atrial and ventricular septa. Approximately 100 years later, an association between congenital cardiac malformations, particularly septal defects, and upper limb deformities was first recognized (594), but it was not until 1960 that familial cases of a heart–hand syndrome were described by Holt and Oram (595). Holt–Oram syndrome (HOS) is characterized by malformed thumbs associated with ASDs, normal intelligence, and normal (i.e. nondysmorphic) features. Essentially all individuals with HOS exhibit some upper limb skeletal abnormality in the developmental distribution of the preaxial radial ray (596,597). These skeletal deformities may be bilateral and asymmetrical or unilateral and, in either limb, may be mild and subclinical or severe and overt. The most common is malformation of one or more carpal bones. The wrist bones may be absent, misshapen, or fused. Another feature, which has been considered to be a typical and expected finding, is a triphalangial or hypoplastic/absent thumb. Some children present with severe foreshortening of the radius that extends proximally in a preaxial distribution to include the humerus and shoulder girdle and may present as phocomelia.

Approximately 75% of individuals with HOS have cardiac manifestations (596) that vary in magnitude from severe to clinically insignificant and are not dependent on the severity of skeletal disease. The cardiac abnormalities may manifest as congenital cardiac structural disease or conduction disease. Most commonly, individuals present with ASDs (usually ostium secundum ASD); many individuals, however, have ventricular septal defects (VSDs), typically in the membranous portion of the ventricular septum. Rarely, more complex congenital heart disease (i.e. tetralogy of Fallot, truncus arteriosus, hypoplastic left heart syndrome, heterotaxia, total anomalous pulmonary venous return) occurs (598–600).

Cardiac conduction abnormality may occur in the presence or absence of structural heart disease, and is commonly progressive. It may manifest initially as sinus tachycardia with mild first-degree AV block, but, over time, the function of the sinus node can deteriorate and, in addition, AV node block can occur. High-grade heart block and AF may occur in patients with HOS (600).

**51.8.2.1 Genetics and Management.** HOS has autosomal-dominant inheritance with complete penetrance (601). The expression of the syndrome, as noted previously, is quite variable, however. The prevalence is believed to be approximately 1 per 100,000 live births.

As 85% of these are new mutations, the mutation rate is calculated to be 1 per million (602).

No consistent familial cytogenetic abnormalities have been associated with HOS although karyotypic abnormalities have been reported in sporadic cases (603,604). Linkage analysis initially identified a locus on chromosome 12q2 in families with HOS (Table 51-3), and subsequent refining studies localized an *HOS* gene to chromosome 12q24.1 (605,606). Cloning of this region identified the human *TBX5* gene (Table 51-3) within this region of the genome, and mutation analysis identified disease-causing mutations (596,607–610). The gene is expressed in skeletal and cardiac tissue, with *TBX5* protein found in the atria, and, similar to the *Nkx2-5* mutations in familial ASD, ventricles and haploinsufficiency appear to be the mechanism of disease in many patients (608,611). In others, it is speculated that dominant-negative effects occur by stoichiometric inhibition of *TBX5* binding to DNA. Genetic heterogeneity exists (609), but the remaining genes are currently unknown.

The management of HOS focuses on treatment of the left-to-right shunt in patients with ASDs or VSDs (potentially requiring diuretics) and ultimately closure of the defect. When more severe congenital heart disease occurs, surgical palliation is required. The conduction disorder must also be monitored closely, and in some cases, a pacemaker is needed.

### 51.8.3 Laterality Defects

The clinical presentation of children with laterality defects is varied (332a,612) and includes abnormal visceral and atrial situs resulting in situs inversus or heterotaxy, abnormal looping of the cardiac tube resulting in ventricular inversion, and abnormal positioning of the heart in the chest (i.e. dextrocardia) (613,614). In some cases, complex cardiac anomalies occur and may be associated with conduction disease (615,616). Conduction defects occur most often in patients with heterotaxy or with “corrected” (left) transposition of the great arteries (L-TGA).

**51.8.3.1 Heterotaxy Syndrome.** The fundamental characteristics of heterotaxy syndrome include abnormal symmetry of the viscera and veins (such as lungs, liver, and vena cava) and situs discordance between various organ systems, as well as between the various segments of the heart (332a,612,617,618). Patients with heterotaxy have a random orientation of various organs, including asplenia or polysplenia syndrome (619) and loss of pulmonary and cardiac asymmetry (isomersion) at some levels, resulting in apparent bilaterally right- or left-sidedness, respectively. Patients with heterotaxy syndromes tend to have significant noncardiac midline defects as well (620,621).

In asplenia syndrome, both lungs are frequently trilobed, both bronchi are eparterial, the spleen is hypoplastic or absent, and the liver commonly overrides

the midline. The cardiac abnormalities found in these patients include right atrial appendage isomerism, common atrium, complete AV canal, double-outlet right ventricle, pulmonic stenosis, TGA, and anomalous pulmonary venous connections (332a,612,622). Atrioventricular block rarely occurs. Several reports of bilateral sinus nodes have been published, and dual AV nodes appear to predispose these patients to SVT, particularly in patients with two ventricles (623). The mechanism for SVT has been postulated to be “AV nodal to AV nodal” reentry, with the retrograde accessory pathway for SVT mapped to an anterior AV node, left lateral pathway, or tricuspid valve.

Polysplenia syndrome includes bilateral left-sidedness with mirror-image lungs (i.e. both lungs have the appearance of the left lung, including two lobes and hyparterial bronchi), anomalous pulmonary venous return, and renal-to-hepatic inferior vena cava segment absence with return of blood from the lower body occurring via the azygos or hemiazygos system (624). Bilateral left atrial appendages may occur, and typical cardiac defects include ASD, VSD, pulmonic stenosis, AV canal, and others. Unlike asplenia, conduction disturbances are common in polysplenia (625), including congenital complete AV block in 20–30% of cases (626,627). The mechanism for AV block has been postulated to be discontinuity between the AV node and the ventricular conduction pathway, usually at the level of the penetrating bundle (628).

**51.8.3.2 Ventricular Inversion.** Isolated ventricular inversion is relatively rare, with the vast majority of patients having associated congenital heart disease. In 99% of cases of ventricular inversion, TGA, resulting in physiologically corrected transposition (L-TGA), is associated (332a,629,630). In addition to L-TGA, other lesions include abnormal left-sided systemic tricuspid valves, malformations of the left-sided systemic right ventricle, VSD, pulmonic stenosis, and dextrocardia. Rhythm disturbances are frequently seen, including preexcitation and atrial tachydysrhythmias, including AF or atrial flutter or SVT (629). In some cases, the dysrhythmias occur because of AV valve regurgitation or ventricular dysfunction, while other cases are due to accessory pathways. Heart block is also common, even in patients with L-TGA only (i.e. no other associated cardiac lesions) (631,632). The site of block may be above, within, or below the His bundle. The AV node is usually located anteriorly in the right atrium of patients with L-TGA that connects right atrium to the His bundle, which encircles the anterior lateral region of the pulmonary valve. In most cases, the posterior AV node is hypoplastic.

#### 51.8.3.1 Genetics.

**51.8.3.1.1 Mouse Models.** Mouse models of aberrant left–right asymmetry have been useful in dissecting the embryologic and genetic basis of laterality. The *inversus viscerum* (iv) mouse, in which heterotaxy occurs

in 50% of homozygous progeny (with the remainder developing normal visceral situs), is due to mutations in the left–right dynein (*lrd*) gene, an axonemal dynein heavy chain gene that is expressed in the embryonic midline along the node and rostral floorplate (633). Another model, the *inv* mouse, has situs inversus in 85% of cases and {of} heterotaxy in 15% of cases of homozygous offspring; in this mouse, the defective gene is an ankyrin-repeat protein called *inversin* (634).

Other mice thus far developed include a model in which *lefty*, a ligand in the transforming growth factor- $\beta$  (TGF- $\beta$ ) pathway that is important for left–right determination, is selectively disrupted (635). In this model, thoracic left isomerism with bilateral left lungs and left atria occurs and appears similar to human polysplenia syndrome. Mice with mutations in the activin receptor type IIB gene develop abnormal spleens and other signs of heterotaxia, as well as bilateral right-sidedness of the pulmonary and atrial anatomy consistent with human asplenia syndrome (636).

**51.8.3.1.2 Human Genetics.** To date, a number of genes have been identified for laterality defects (637). In X-linked heterotaxy, Gebbia et al. (638) identified mutations in *Zic3*, a zinc-finger transcription factor that functions in the early stages of left–right body axis formation (Table 51-3). In autosomal-dominant forms of disease, mutations in the human activin type IIB gene (639), *NODAL*, *LEFTY* (640), and *HNF-3 $\beta$* , all transcription factors (Table 51-3) that are members of the TGF- $\beta$  pathway, have been identified in patients with laterality defects (641,642). (Most recently, Robinson et al. (593) identified mutations in *CRELD1*, a cell adhesion molecule mapped to chromosome 3p25, as causative of heterotaxy associated with ASDs.)

## 51.8.4 Familial MVP

**51.8.4.1 Clinical Features.** MVP is a very common clinical diagnosis, particularly in young, healthy women (329a). The diagnosis is usually made on the basis of auscultatory findings of a midsystolic click with or without a mitral regurgitation murmur heard at the cardiac apex (329a,361a). Echocardiography may identify the valve cusps prolapsing into the left atrium during systole and the redundant valve leaflets; in cases of mitral regurgitation, Doppler and color Doppler may clearly demonstrate the regurgitant jet. Typical symptoms include chest pain, palpitations, and anxiety. Dysrhythmias are common. The dysrhythmias occurring in the MVP syndrome include atrial premature complexes, nonsustained atrial tachycardia, and nonsustained ventricular ectopy. It has been speculated that MVP has an associated increased risk of sudden death, possibly due to dysrhythmias; severe mitral regurgitation and ruptured mitral chordae tendineae have also been cited as causes of sudden death. In addition, these patients have an increased risk of endocarditis.

**51.8.4.2 Genetics and Management.** MVP is commonly inherited, with autosomal-dominant transmission seen (643). Expression may be variable, depending on age and gender. Full expression is found in adolescent and young adult women (11–50 years of age), affecting approximately 50% of this population in families with MVP. On the other hand, only 10–30% of older women, older men, and children in affected families demonstrate MVP, consistent with incomplete penetrance.

Linkage to chromosome 16 at 16p11.2–p12.1 (Table 51-3) was first identified in families with MVP in 1999 (644). Interestingly, males and females were equally affected clinically. This gene for this form, *MVP1*, has not yet been identified, but we speculated that a connective tissue protein-encoding gene would be at the root of the abnormality (645). MVP commonly accompanies connective tissue disorders, such as Marfan syndrome and Ehlers–Danlos syndrome, which have been shown to occur because of mutations in fibrillin and various collagens. It is likely that MVP syndrome is a forme fruste of a connective tissue disorder (645). More recently, linkage has been reported in familial MVP (MVP2) on chromosome 11p15.4 (646), while a third locus on Xq28 was reported in a familial form of inherited myxomatous valvular dystrophy (647) in which degeneration of the aortic valve was also noted. The genes for MVP2 and the X-linked disorder have not yet been identified.

## 51.9 SUMMARY

The genetics of cardiac diseases, including those in which dysrhythmias are primary or secondary findings, has come of age as the twenty-first century begins. As the Human Genome Project comes to completion, it is expected that further understanding of the genes responsible for the disorders of the heart will also be better understood. In the next decade, the relationships between mutated genes, modifier genes, and environmental factors are likely to be important areas of study that will enable better therapies to be developed.

### Biography

Reed Pyeritz completed his PhD and MD at Harvard and trained in internal medicine at the Peter Bent Brigham Hospital in Boston and medical genetics at the Johns Hopkins Hospital in Baltimore. He is a professor of Medicine and Genetics at the Raymond and Ruth Perelman School of Medicine of the University of Pennsylvania in Philadelphia, where he directs the Center for the Integration of Genetic Healthcare Technologies and serves as vice-chair for academic affairs of the Department of Medicine. He is a senior fellow in both the Center for Bioethics and the Leonard Davis Institute for Health Economics.

His research has focused on several areas, including clinical investigations of heritable disorders of connective tissue and cardiovascular diseases, especially those affecting the thoracic aorta. Currently he is studying how more refined methods of investigating genetic variation, such as cytogenomic arrays and whole genome sequencing, actually increase the level of uncertainty in applying the results clinically.

## Genetics of Blood Pressure Regulation

*Frank S Ong, Kenneth E Bernstein, and Jerome I Rotter*

Cedars-Sinai Medical Center, Los Angeles, CA, USA

This article is a revision of the previous edition article by Xavier Jeunemaitre, Anne-Paule Gimenez-Roqueplo, Sandra Disse-Nicodeme, Pierre Corvo, volume 2, pp 1283–1300, © 2001, Elsevier Ltd.

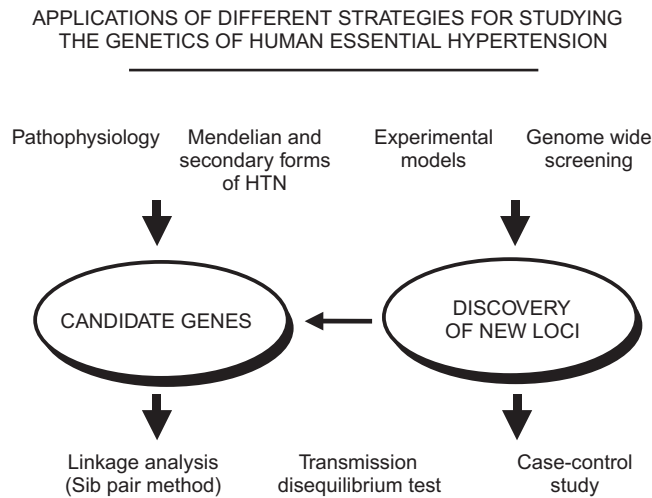

### 52.1 INTRODUCTION

Hypertension, or high blood pressure, is the leading cause of cardiovascular disease worldwide and is highly prevalent in the United States and around the world. The overall prevalence of hypertension in the United States is approximately 29% (1,2). As expected, the majority of hypertension is accounted for by people older than 60 years of age; however, the prevalence of hypertension among younger people is far from negligible—7.3% prevalence in ages 18–39 and 32.6% prevalence in ages 40–59 (3). Even though there has been some improvement in blood pressure control in both sexes, non-Hispanic blacks, and Mexican-Americans in recent years, the prevalence of hypertension has not declined (3). Hypertension is defined as blood pressure >140/90 mmHg and prehypertension as blood pressure between 120 and 139/80 and 89 mmHg (4). About 90–95% of hypertension cases have no obvious underlying medical cause and are referred to as primary “essential” hypertension, whereas the remaining 5–10% are caused by other conditions that affect the kidney, arteries, heart or endocrine system (5).

A number of epidemiologic studies have shown that individual blood pressure levels result from both genetic predisposition and environmental factors. Aside from the well-known environmental factors such as obesity, lack of exercise, smoking, stress, excessive sodium consumption, and excessive alcohol consumption, other attributes such as family history also play a part in causing essential hypertension. The heritable component of blood pressure has been documented in familial and in twin studies. However, the total number of genetic loci involved in hypertension, the frequency of deleterious alleles, their mode of transmission, and the quantitative effect of any single allele on blood pressure remain unclear. The unimodal distribution of blood pressure

within each age group and in each sex strongly suggests that multiple loci are involved. Several strategies based on the biological tools available at the genetic level and on different approaches for comparing hypertensive and normotensive subjects (case-control studies, family-based association studies, sibling pairs studies) have been used to identify major genes or suggest susceptibility genes. The discovery of a positive linkage between a given locus and the high blood pressure promotes new studies for finding a functional gene variant and for identifying new intermediate phenotypes associated with the locus. Multiple genes have been identified as risk factors for hypertension, but even so, only a fraction of the heritability is sufficiently explained (6).

During the past twenty years, numerous investigators have attempted to identify the genes involved in blood pressure regulation, their respective importance in determining blood pressure level, and sometimes their interaction with other genes and environmental components. Different strategies have been undertaken (Figure 52-1). The first and most successful approach, mainly taken by Lifton et al. (7–9), was to identify genes causing rare Mendelian forms of hypertension. This has led to the confirmation of the importance of some enzymes, channels, and receptors implicated in sodium handling in the regulation of blood pressure. The second approach was to study genes that may contribute to the variance of blood pressure because of their well-known effect on the cardiovascular system. The genes of the renin–angiotensin–aldosterone system are a good illustration of such a “candidate gene” approach since this system is involved in the control of blood pressure and in the pathogenesis of several forms of experimental and human hypertension. The third approach has been the genome-wide association studies (GWAS), with genotyping of genetic

**FIGURE 52-1** Main strategies used for studying the genetics of arterial hypertension. (Revised by Reed E. Pyeritz, April 2006.)

markers and analyzing their cosegregation with blood pressure. With the advent and ever-decreasing cost of next-generation sequencing, recent developments in the genetics of hypertension involve exome sequencing and will eventually incorporate whole-genome sequencing. There have also been numerous fruitful research performed based on experimental rodent models on the genetics of blood pressure regulation (10–14).

There are several risk factors and sequelae of high blood pressure. A major factor is an imbalance of the renin–angiotensin–aldosterone system. Renin converts angiotensinogen to angiotensin I, which is further converted by the angiotensin-converting enzyme (ACE) to angiotensin II. Angiotensin II is responsible for the constriction of blood vessels as well as the production of aldosterone, which promotes fluid retention. Both angiotensin II and aldosterone increase blood pressure, and therefore, promote hypertension. There are cases, though, where renin is not overproduced, and patients with this sort of hypertension are said to have “low-renin” hypertension. Vascular remodeling, a result of the increased resistance in blood vessels required to push the blood through due to increased pressure, is precarious as even a small amount of blockage greatly reduces blood flow rate. Such blood vessel blockage was found in 34% of hypertensive patients in a study comparing arteries of hypertensives versus normotensives (15). Vascular inflammation also plays a great part in the pathophysiology of hypertension, increasing blood pressure through restricting blood flow by constricting blood vessels. High blood pressure promotes inflammation through the release of vasoactive peptides such as angiotensin-II and endothelin-1, resulting in a detrimental feedback loop (16,17). Carotid intima-media thickness (cIMT), commonly used as a surrogate for atherosclerosis, is also correlated with hypertension and microalbuminuria and GWAS has contributed in identifying substantial genetic contribution to systolic blood pressure (SBP), renal function, and cIMT (18).

Salt-sensitive patients have a greater risk of developing renal failure and other cardiovascular issues. The main reason for this renal failure due to high salt intake is a decrease in blood flow inside the kidneys. Since the blood flow has decreased, the kidneys must increase their filtration fraction so as to continue blood regulation (19). In salt-resistant subjects, changes in plasma volume and cardiac output had no significant effect on blood pressure as the blood vessel dilates to compensate, whereas in salt-sensitive subjects, the rise in sodium resulted in a steady increase in blood pressure with no vasodilation (20). Sodium intake itself is found to be correlated to increased arterial pressure. High salt intake, however, does not increase the volume of blood in blood vessels in patients with essential hypertension. In fact, the blood volume is decreased in such patients, and the blood pressure increase is a consequence of increased intracellular sodium, and consequently, intracellular calcium. This results in increased flow resistance inside blood vessels and increased blood pressure (21). Furthermore, chronic kidney disease (CKD) itself is a significant risk factor for hypertension. For every 100mEq/g increase in urinary sodium, there is a 1.61-fold increase in risk for progression of patients to end-stage renal disease (22). In a study of non-CKD and CKD patients, patients with cardiovascular disease were found to have a significantly greater arterial stiffness (23). This stiffness, in turn, increases vascular resistance, and therefore, increases blood pressure. Recently, variants in the *LSD1* gene were found to be associated with salt-sensitive hypertension in African-American hypertensive cohort and functional studies were also carried out in *LSD1*-knockout mice (24).

The dangers of dyslipidemia are widespread, including increased risk of atherosclerosis and consequently, increased blood pressure, heart disease, and stroke (25). Atherosclerotic plaque blocks blood flow and this blockage results in oxygen starvation and increased blood pressure. In severe cases, starved tissues may undergo necrosis, or blood vessels may rupture. Furthermore, cholesterol levels were found to be a principle risk factor for cardiovascular disease in a study measuring blood pressure response during exercise for over 2100 subjects (26). In a study of 3110 men without hypertension, men with dyslipidemia had an increase of 23% in their risk of developing hypertension (27). One of the first genome-wide scan for genes contributing to blood pressure was conducted in a set of 18 Dutch families exhibiting familial combined hyperlipidemia with the revelation of a locus on chromosome 4 that exhibited a significant logarithm of the odds (LOD) score of 3.9 (and 4.6 when adjusted for age and gender) with SBP (28). In the same study, there was also a suggestive evidence of linkage of diastolic blood pressure to the lipoprotein lipase gene locus on chromosome 8p with a LOD score of 1.8 (28). Prehypertension is also associated with high triglycerides and low-density lipoprotein (LDL) in both females and males (29).

In nondiabetic individuals with hypertension, insulin resistance is a common finding. In a study of untreated patients with essential hypertension, glucose uptake was found to be inversely proportional to mean blood pressure (30). Since glucose uptake is hindered by insulin resistance, the higher the insulin resistance, the lower the glucose uptake, and therefore, the higher the blood pressure (30). Correlation and pathway analysis examining relationships among traits within and between generations found that genetic effects unrelated to body mass index (BMI) accounted for 60.8% of the variation in SBP and 36.8% of the variation in insulin sensitivity, whereas heritable effects related to BMI accounted for an additional 14% of variation in SBP and 26.8% of variation in insulin sensitivity (31). One of the first studies to successfully identify the genetic loci responsible for variations in blood pressure was a quantitative sibpair linkage analysis with candidate loci for blood pressure control, insulin resistance and lipid metabolism. A genetic region at the lipoprotein lipase (LPL) locus on the short arm of chromosome 8 was found to be linked to SBP (32). Further studies demonstrated that LPL haplotypes showed linkage to glucose infusion rate, a direct physiologic measurement of insulin sensitivity, in a family-based population of Mexican-Americans (33). Later, another study independently replicated this finding that LPL haplotypes 1 and 4 are associated with insulin sensitivity and resistance (34). In addition, it was suggested that variation in the 3' untranslated region of LPL affects LPL expression and activity, consequently influencing risk of insulin resistance (35).

A blood pressure and insulin resistance relationship was further elucidated with additional genetic linkage studies, including the finding of a major gene in chromosome 7q linked to blood pressure, leptin levels, and homeostasis assessment (HOMA) (36). Later, it was found that genes in the blood pressure pathway, namely *ADD1*, *ADRB2*, *AGT*, *NOS3*, *NPPA*, and *SCNN1A*, may be the genetic markers for insulin resistance in the Mexican-American Coronary Artery Disease cohort (37). In the Insulin Resistance Atherosclerosis family study, it was further determined that both albuminuria and blood pressure exhibit familial aggregation in nondiabetic Hispanic- and African-Americans (38). In the same cohort, it was also concluded that a significant relationship exists between visceral adipose tissue and hypertension in men with insulin resistance (39). A good example of gene discovery without genome-wide screening, but with careful multivariate subanalyses is the finding that variations in the *CAV1* gene are associated with insulin resistance and hypertension (40).

## 52.2 MENDELIAN FORMS OF HYPERTENSION

Rare Mendelian forms of hypertension are usually characterized by early-onset hypertension, frequent familial history of stroke, and strong penetrance. Most forms

are also characterized by extracellular volume expansion leading to a suppression of plasma renin activity, confirming the importance of salt and water homeostasis in blood pressure regulation (41).

### 52.2.1 Mutations Affecting Circulating Mineralocorticoid and Its Receptor

**52.2.1.1 Glucocorticoid-Remediable Aldosteronism (OMIM #103900).** In glucocorticoid-remediable aldosteronism (GRA), also referred to as glucocorticoid-suppressible hyperaldosteronism (GSH) or familial hyperaldosteronism type I, there is a variable degree of hyperaldosteronism and an increased urinary excretion of 18-hydroxylated and 18-oxocortisol metabolites, 18-hydroxycortisol and 18-oxocortisol. These abnormalities, including hypertension, can be corrected by the suppression of adrenocorticotrophic hormone (ACTH) by dexamethasone. It had been proposed that the disease was due to an abnormality of aldosterone synthase—CYP11B2, the enzyme responsible for the conversion of corticosterone into aldosterone—in the zona fasciculata. Lifton et al. showed that this disorder was linked to an abnormal aldosterone synthase gene (8). They studied a large kindred and found a gene duplication arising from unequal crossing-over, resulting in fusion of the 11 $\beta$ -hydroxylase (CYP11B1) promoter with the coding sequence of aldosterone synthase. The chimeric gene encodes a protein that can hydroxylate cortisol (the steroid substrate present in the zona fasciculata) in the 18 position. This gene is under the control of 11 $\beta$ -hydroxylase gene regulatory region, whose expression is under ACTH control and can be downregulated by exogenous glucocorticoid administration. All the phenotypic abnormalities of GSH could be explained by this mutation.

Since this original description, a few other families affected with this syndrome have been identified (42). In a case of GSH with an adrenal tumor, expression of the chimeric gene was found in the tumoral tissue and in the zona fasciculata of the surrounding adrenal tissue, and sensitivity of the corresponding adrenal cells to ACTH was observed (43). In all families reported thus far, the chimeric gene derives from unequal homologous recombination between exons 2 and 4 of the 11 $\beta$ -hydroxylase and aldosterone synthase genes, respectively. It has been shown by site-directed mutagenesis that such hybrid genes expressed in heterologous eukaryotic cells are able to encode chimeric proteins that hydroxylate cortisol in the 18 position (44). More recently, the transfection into COS-7 cells of a series of CYP11B1 complementary DNAs (cDNAs) containing various regions of CYP11B2 sequence showed that two amino acid changes, Ser-288Gly and Val320Ala, are sufficient to convert CYP11B1 into an efficient aldosterone-producing enzyme (45). Although these results suggest that a gene conversion involving exons 5 and 6—in which these residues

are encoded—could cause a novel form of GSH, no such molecular abnormalities have yet been found in a series of patients with essential hypertension and primary aldosteronism (46,47). GSH is very rare; however, one of the major interests of this diagnosis is its therapeutic implication, with a clinical and biological improvement with small doses of dexamethasone that can be associated with an antialdosterone treatment and/or a more usual antihypertensive therapy (48,49).

Gordon et al. described another form of familial primary aldosteronism, called familial hyperaldosteronism type II (FH-II), that corresponds to few families, with about 30% of the affected patients presenting an aldosterone-producing tumor and with probably an autosomal-dominant inheritance (50,51). The screening of the entire genome in a large family with FH-II showed linkage with chromosome 7p22; a gene has not been identified (52).

**52.2.1.2 Hypertension, Early-Onset, Autosomal-Dominant, with Exacerbation in Pregnancy (OMIM #605115).** In the family described by Geller et al., all women bearing the mutation had severe pregnancy-induced hypertension with hypoaldosteronism, which was probably caused by the massive increased production of progesterone during pregnancy (53). This condition is characterized by an early-onset and severe form of hypertension associated with low plasma levels of renin and aldosterone (53). It is caused by an activating missense gain-of-function mutation (Ser810Leu) of the human mineralocorticoid receptor. This mutation is located within the hormone-binding domain and results in constitutive mineralocorticoid receptor activity and an alteration of the receptor specificity. The receptor becomes abnormally activated by progesterone and other steroids lacking 21-hydroxyl groups, which act normally as antagonists. These original findings open the possibility of such mutations underlying some cases of pregnancy-induced hypertension.

**52.2.1.3 Apparent Mineralocorticoid Excess (OMIM #218030).** The syndrome of apparent mineralocorticoid excess (AME) is a rare autosomal recessive form of hypertension diagnosed in children and characterized by very early and severe hypertension associated with hyporeninism and hypoaldosteronism (54). It corresponds to a defect of 11 $\beta$ -hydroxysteroid dehydrogenase type 2, which is expressed in the kidney and converts cortisol into cortisone and corticosterone into 11-dehydrocorticosterone. Classical deleterious mutations have been found in affected patients who are either homozygotes for the mutation, especially in consanguineous families, or composite heterozygotes (55–57). The enzymatic defect leads to increased renal concentrations of cortisol and corticosterone, which are themselves powerful agonists of the human mineralocorticoid receptor, contrary to cortisone and 11-dehydrocorticosterone. Thus, affected patients are characterized by high values of the cortisol:cortisone ratio in plasma and urine, and by arterial hypertension, mimicking primary aldosteronism (58). The genetic diagnosis

can be obtained rapidly by direct sequencing of the five exons of the gene.

**52.2.1.4 Pseudohypoaldosteronism Type IIA (OMIM #145260).** Pseudohypoaldosteronism type II (PHA-II), also known as *Gordon syndrome*, is an autosomal-dominant form of volume-dependent hypertension characterized by hyperkalemia and hyperchloremic acidosis without any glomerular insufficiency (59). The low renin levels are thought to be the consequence of volume repletion, whereas plasma aldosterone seems to vary according to the opposite influences of low renin and high potassium levels. At least two arguments suggest a primary renal tubular defect along the distal convoluted tubule: affected patients are highly sensitive to small doses of thiazide diuretics; and the features of PHA-II are the mirror image of the Bartter–Gitelman syndrome, in which inactivating mutations in the thiazide-sensitive sodium chloride cotransporter gene (*SLC12A3*) have been demonstrated (60). However, the pathophysiology of PHA-II is certainly more complex, and other authors have proposed an associated reduced proximal reabsorption, a chloride reabsorption defect, and an altered sensitivity to mineralocorticoids (61). Lifton et al. discovered mutations in *WNK4*, which maps to 17q21–q22, in several families with this form of pseudohypoaldosteronism, including a family originally reported to show linkage to chromosome 12 (62,63).

**52.2.1.5 Hypertension with Brachydactyly (OMIM #112410).** A rare form of an autosomal-dominant syndrome associating arterial hypertension and brachydactyly has been reported in a few families, especially one extended Turkish pedigree (64,65). In 100% of the affected patients, hypertension is accompanied by short stature and brachydactyly but with no other special biological or hormonal phenotype (66). A particular defect of cerebral vascularization—loops in the posterior/inferior cerebellar artery—has been discussed as the possible origin of neurovascular compression and high blood pressure (67). The gene responsible for the disease was mapped to chromosome 12p but has not yet been identified (68,69).

## 52.2.2 Mutations Altering Renal Ion Channels and Transporters

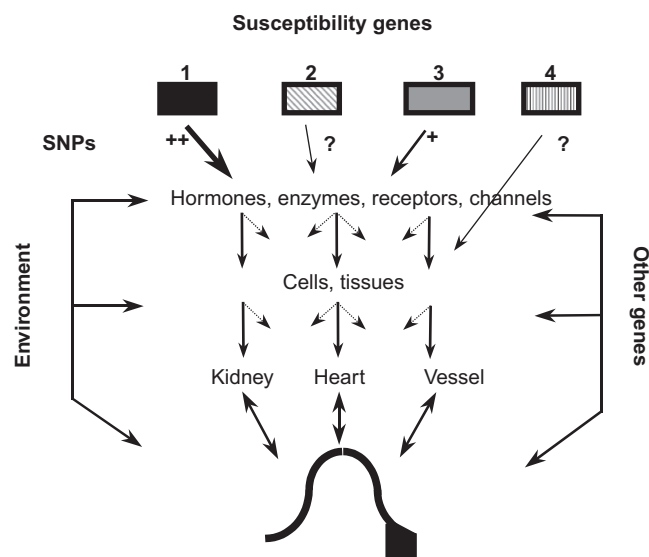

**52.2.2.1 Liddle Syndrome (OMIM #177200).** Liddle and associates described a family with hypertension and an abnormality of Na<sup>+</sup> reabsorption at the level of the renal distal tubule, which simulated primary aldosteronism but had negligible basal and stimulated aldosterone secretion (70,71). Blood pressure and hypokalemia were not influenced by spironolactone treatment, however, triamterene, a specific inhibitor of the distal renal epithelial sodium channel, corrected these abnormalities. The authors proposed that the primary abnormality was a constitutive activation of the epithelial sodium channel. Some 30 years later, this hypothesis was reinvestigated in the proband and originally described pedigree. The index

case developed renal failure and renal transplantation corrected the aldosterone and renin response to salt restriction, showing the involvement of the kidneys in the disease, and making the gene for the epithelial amiloride-sensitive sodium channel (ENaC) located in the collecting cortical tubule a logical candidate gene for this disease (72). This channel consists of at least three homologous subunits,  $\alpha$ ,  $\beta$ , and  $\gamma$ , which act together to confer its low sodium conductance and its high selectivity for sodium and amiloride (73).

Loss-of-function mutations of the gene for either the  $\beta$  or the  $\gamma$  subunits of the ENaC result in the recessive form of pseudohypoaldosteronism type I, characterized by excessive salt wasting accompanied by hyperkalemic acidosis, increased plasma and urinary aldosterone, and increased plasma renin activity (74). Analyzing the original Liddle pedigree, which demonstrated autosomal dominant inheritance, Shimkets et al. showed complete linkage of the gene encoding the  $\beta$  subunit of this channel, located at chromosome 16p13–12 (75). In this pedigree and in other unrelated kindreds, a premature stop codon, a frameshift mutation, and other deleterious mutations were found, all located in the last exon of the gene encoding for the intracellular carboxy-terminal domain of the  $\beta$  subunit (75). These mutations were showed to be gain-of-function mutations, with an increased amiloride-sensitive  $\text{Na}^+$  current after transfection of the corresponding mutant subunits together with  $\alpha$  and  $\gamma$  wild-type subunits. In a Portuguese family affected with this syndrome, a 32-bp deletion leading to a premature termination of the carboxyl end of the same subunit was found (76,77). A point mutation affecting the same region of the  $\gamma$  subunit has also been found to cause Liddle syndrome, but no mutation of  $\alpha$ -ENaC has been discovered (68). Comprehensive studies have shown that the mechanism by which truncation of the C-terminus of the  $\beta$  and  $\gamma$  subunits alters the function of the epithelial sodium channel corresponded to a much conserved motif (PPXXY) in the C-terminus of all three subunits of the sodium channel (78–80). Normally, a specific interaction between the PY motif and cytosolic proteins (Nedd4 and other related WW proteins) leads to degradation of part of the newly synthesized subunits (81). Both deletion and missense mutations of this PY motif increased surface expression of the mutant proteins and thus increased the number of sodium channels in the apical membrane, favoring renal sodium absorption and hypertension (82).

## 52.3 CANDIDATE GENES

Although it is likely that genes interact with each other and with environmental factors (Figure 52-2), most of the studies performed so far have been conducted using a very simple design, only testing the possible role of each candidate gene—that is, each gene coding for a protein (hormone, enzyme, receptor, channel, etc.) known to be involved in blood pressure regulation.

**FIGURE 52-2** Interaction between genes and environment in the regulation of blood pressure.

### 52.3.1 Renin–Angiotensin System

The importance of the renin–angiotensin system in the salt and water homeostasis and in the regulation of vascular tone, as well as the effectiveness of inhibitors of this system in the treatment of hypertension and of its morbid consequences, has justified the genetic analysis of this system for many years. All the genes of the human renin–angiotensin system have been mapped and cloned, and genetic markers were identified. Since very complete reviews have already been published on this subject, we only summarize the main findings obtained that concern essential hypertension, blood pressure regulation, or both (83–88).

**52.3.1.1 The Renin Gene (OMIM \*179820).** The renin gene (*REN*; 1q32) is important because the renin–angiotensinogen reaction is the first and rate-limiting step leading to angiotensin II (Ang II) production. Numerous studies have involved renin to some degree in experimental forms of hypertension and in human hypertension. This was especially the case in the fulminant hypertension that develops in transgenic rats harboring the mouse *ren2* gene and of the pioneer observation made by Rapp et al. of cosegregation between a renin gene polymorphism and blood pressure level in Dahl rats (89,90). In humans, about 30% of subjects with essential hypertension have higher renin levels compared to normotensive subjects of the same age when examined under the same metabolic conditions (91). Interestingly, renin levels seem at least partly heritable as observed by Grim et al. in twins submitted to very standardized conditions of posture and sodium diet, and confirmed by Rossi et al. (92,93). The analysis of 175 sibling pairs and trios who participated in a multicenter trial showed very significant correlations of plasma renin levels either on a high-salt or a low-salt diet (94).

Association studies (most of which being of limited power) performed with several polymorphisms of *REN*

largely have been negative (85,95–97). To explore the potential role of the renin gene as a genetic determinant of hypertension, Jeunemaitre et al. analyzed the same renin gene haplotypes in 98 sibling pairs with severe essential hypertension (98). Allelic concordance for all sibpairs according to sibship size was not significantly different from that expected under the hypothesis of no linkage, reflecting only a small excess of renin alleles shared by the hypertensive sibs. These results suggest that REN does not have a frequent and/or important role in the pathogenesis of essential hypertension. However, the definitive exclusion of a contribution of the renin gene in the heritability of essential hypertension will require more powerful linkage studies, such as the use of a reliable renin intermediate phenotype, and a more informative marker of the renin locus. Some of the recent genome scans have found the chromosome 1q32 region to be a possible locus for hypertension.

**52.3.1.2 Angiotensin I-Converting Enzyme Gene (OMIM +106180).** Angiotensin I-converting enzyme (ACE) is a zinc metalloprotease whose main functions are to convert angiotensin I into angiotensin II and to inactivate bradykinin. It is assumed that this step of the renin–angiotensin system is not rate limiting in plasma, and indeed there is no indication that plasma ACE levels are directly related to blood pressure levels. However, the local generation of angiotensin I and the degradation of a bradykinin may depend on the level of ACE expressed in tissues. Molecular cloning of the human endothelial ACE cDNA revealed that the enzyme consists of two highly homologous and functionally active domains resulting from gene duplication (96). The organization of the human ACE gene (17q23) provides further support for the duplication of an ancestral gene (99). Ong et al. have made the recent discoveries that mice lacking the N-domain of ACE have increased response to angiotensin-II induced hypertension, increased inflammatory cytokines, and protection against bleomycin-induced pulmonary fibrosis (100,101). There are two ACE promoters, a somatic promoter localized 5' to the first exon of the gene and a germinal intragenic promoter located 5' to the specific testicular ACE messenger RNA (99,102,103). The two alternate promoters of ACE exhibit highly contrasting cell specificities as the somatic promoter is active in endothelial, epithelial, and neuronal cell types, whereas the testis promoter is only active in a stage-specific manner in male germinal cells (102). It is thought that plasma ACE concentration reflects the level of the synthesis of the enzyme at the somatic level. Bernstein et al. have made many discoveries in this area, elucidating both the traditional and nontraditional roles of ACE (14,104–107).

For a geneticist, one of the big advantages of plasma ACE concentration as a genetic marker is its large inter-individual variation (from 1 to 8 at the extremes of the distribution) and its reproducibility when measured repeatedly in a given subject (108). This important

interindividual variability is due, in large part, to a major genetic effect, as shown by Cambien et al. in a family population study, in which there was an intrafamilial resemblance between plasma ACE levels accounting for approximately 30% and 75% of the ACE variance in parents and offspring, respectively (109). The role of ACE in the genetic control of plasma ACE was assessed using an ACE polymorphism consisting of the presence or the absence of a 287-base pair DNA fragment (insertion [I]/deletion [D]) (110). In this seminal observation of 80 healthy subjects, Rigat et al. showed that DD subjects had an immunoreactive ACE level almost twice as high as patients homozygous for the I allele, whereas heterozygous patients had an intermediate ACE level. This I/D polymorphism accounted for 47% of the total variance of serum ACE, showing that the ACE locus plays an important role in determining serum ACE levels (110). Similar to serum, T-lymphocyte ACE levels are significantly higher in patients homozygous for the D allele than in the other subjects (111). The ACE I/D polymorphism is not directly involved in the genetic regulation of serum and tissue ACE, and the causative variant responsible for the increase in ACE has yet to be found; indeed, another study combining segregation and linkage analysis in 98 healthy nuclear families showed that the ACE I/D polymorphism is only a neutral marker in strong linkage disequilibrium with the putative functional variant (112). Soubrier's group performed an extensive study of eight new polymorphisms in 95 healthy nuclear families (113). After adjustment for the I/D polymorphism, all polymorphisms of the 5' group remained significantly associated with ACE levels, which suggested the existence of two quantitative trait loci acting additively on ACE levels and which would explain 38% and 49% of the ACE variance in parents and offspring, respectively. More recently, Rieder et al. analyzed the complete genomic sequence of ACE from 11 individuals, representing the longest contiguous scan (24kb) for sequence variation in human DNA. They identified 78 variable sites in 22 chromosomes that resolved into 13 distinct haplotypes; 17 of these chromosomes were in absolute linkage disequilibrium with the ACE I/D polymorphism, producing two distinct and distantly related clades and suggesting that the causal variant should be located within the 3' part of the gene (114).

The observation that plasma ACE levels are under the direct control of genetic variation in ACE, coupled with the role of the ACE enzyme in two main enzymatic cascades (renin–angiotensin system and kallikrein–kinin system) in cardiovascular physiology, rapidly made the ACE I/D polymorphism one of the most popular markers tested in cardiovascular diseases. The first genome scans, performed in an F2 rat population generated from stroke-prone spontaneously hypertensive rats and normotensive genetically hypertensive rats, made this hypothesis even more attractive (115,116). Both groups of investigators found a significant linkage between NaCl-loaded

hypertension and a gene locus on rat chromosome 10 that contained the ACE locus and contributed as much as 20% of blood pressure variance under high salt intake. Several hundred reported and unreported studies have been performed since then (85,87,88). We summarize here only some of the main findings using ACE as a candidate gene for human essential hypertension.

One association study comparing a normotensive and a hypertensive Australian population with two hypertensive parents showed an association of hypertension with an ACE polymorphism (117). In fact, the significant difference between the I/D genotype originated only from a subgroup of patients of age 50 years or older, in which the D genotype was less frequent than in normotensives. This finding was interpreted as owing to an overrisk of cardiovascular events in hypertensive patients carrying the D allele (118). Harrap et al. investigated the distribution of the ACE I/D gene polymorphism described previously in young adults with contrasting genetic predisposition to high blood pressure (the “four-corners approach”) (119,120). Young adults with high blood pressure and two parents with high blood pressure did not show any significant difference in the I/D allele frequencies of ACE when compared with adults of the same age but with low blood pressure and no genetic predisposition to high blood pressure. Other association studies were also negative (121,122). In a large series of hypertensive sibpairs from Utah, no evidence of linkage between hypertension and a growth hormone gene polymorphic marker in complete linkage disequilibrium with ACE emerged (123).

However, some studies suggested that ACE might influence blood pressure variability in a sex-specific manner. In a logistic regression analysis of 3095 participants in the Framingham Heart Study, the adjusted odds ratios for hypertension among men for the DD and DI genotypes were 1.59 and 1.18, respectively, versus II, where no effect was observed in women (124). Positive results were also observed by Fornage and associates in the analysis of a large population-based sample of 1488 siblings having a mean age of 15 years and belonging to the youngest generation of 583 randomly ascertained three-generation pedigrees from Rochester, Minnesota (125). In sex-specific analyses, genetic variation in and around ACE explained as much as 35% of the interindividual blood pressure variation in males but not in females. Finally, Julier et al. conducted an affected sibpair analysis in French and U.K. families, based on the fact that one of the principal blood pressure loci in rat hypertensive strains lies on chromosome 10, a region homologous to human chromosome 17 (126). Significant evidence of linkage was found near two closely linked microsatellite markers, D17S183 and D17S934, that reside 18 cM proximal to ACE in the homology region (126). Taken together, these results suggest that genetic variation in ACE does not play a major role in blood pressure variance in the overall population, but that it could influence

variation either in a sex-specific manner or indirectly by its role in different tissues (kidney, heart, vessels) (85,87,88).

**52.3.1.3 The Angiotensinogen Gene (OMIM +106150).** Angiotensinogen (angiotensin I; AGT), the renin substrate, is mainly synthesized by the liver and is the unique substrate for renin. Plasma angiotensinogen concentration is within a range, in which variations in its concentration directly affect the angiotensin I production rate. Indeed, angiotensinogen levels are around the K range of renin, and therefore, it is logical to suspect that a chronic state of increased plasma angiotensinogen might increase angiotensin I and facilitate hypertension and/or cardiovascular diseases. The role of angiotensinogen in human hypertension was suspected in an epidemiologic study in which a strong correlation was found between plasma angiotensinogen concentration and blood pressure, and in another study in which offspring of hypertensive patients had elevated plasma angiotensinogen levels (127,128).

The human angiotensinogen gene (AGT) belongs to the superfamily of serpins and is localized to chromosome 1q42.3, in the same region as human renin (129,130). Jeunemaitre et al. suggested a role of AGT in human essential hypertension (131). An extensive study was performed in two large series of hypertensive sibships yielding a total of 379 sibpairs (Salt Lake City, Utah, USA and Paris, France) and using a highly polymorphic microsatellite marker at AGT. An excess of AGT allele sharing was found mainly in severely hypertensive sibpairs and in men. Other linkage studies have since been reported with discrepant results. Caulfield et al. showed a strong linkage and an association of AGT to essential hypertension in a set of British families (132,133). To the contrary, no evidence for linkage was found in a large European study involving 630 affected sibling pairs, either in the whole panel or in family subsets selected for severity or early onset of disease (134). Linkage of AGT to essential hypertension was also found in 63 affected African–Caribbean sibling pairs (135).

Similarly, positive albeit modest significant excess of AGT allele sharing was found in 46 extended Mexican–American families (136). No linkage was found between AGT and hypertension in 310 hypertensive Chinese sibling pairs (137,138). Together, these results probably highlight the modest effect of AGT in the overall population and the difficulty of identifying susceptibility genes by linkage analysis in complex diseases.

Among the 15 polymorphisms initially identified, two of them leading to amino acid changes, 174M and M235T, were found to be associated with hypertension and with plasma angiotensinogen concentration (98,123,131). This association between plasma angiotensinogen level and the M235T genotype was further confirmed in white children (139). In this study, a strong and independent relationship of serum angiotensinogen with BMI and race was also observed.

Confirmation of the impact of an increased effect of angiotensinogen on blood pressure was obtained by Smithies et al., who performed genetic manipulations in mice leading to animals with several functional copies of a given gene (13). Mice bearing one, two, three, or four functional *AGT* copies displayed a gene-dosage effect on plasma angiotensinogen concentration and blood pressure level, paralleling the M235T variant effect observed in humans (140,141). The threonine residue at position 235 is not conserved across species and is in complete linkage disequilibrium with another nucleotide substitution (G > A) at position 6 in the promoter of the gene, both alleles being indistinguishable (77). Lalouel and his group were able to show that this variant is associated in vitro with increased expression of *AGT* and probably explains the association with increased plasma angiotensinogen (142). However, the true biologic effect may be more complex since other polymorphisms (C-532T, C-18T, A-20C, T+31C) also in linkage disequilibrium with G-6A and M235T might play a role in the variation in transcription of the gene (143–146).

There is a strong effect of race on the allele frequency of most of these polymorphisms. The 235T allele frequency varies from 40% in whites to 80% in the Asian and African-American populations and as much as 93% in Nigerians (43). This high prevalence of the 235T allele may explain why no relation between 235T or 174M allele frequencies and hypertension was observed in a study of African-Americans (147). In the Japanese population, a significant association between this allele and high blood pressure was found in several separate case-control studies (148–151). These differences in allele frequencies might also facilitate false-positive results in case of admixture in the case-control studies (152). The association between the M235T polymorphism and essential hypertension has been tested in a large number of case-control studies (153). A meta-analysis of case-control studies representing 5493 white patients showed that the *AGT* 235T allele was significantly but mildly associated with hypertension and this association increased in studies with positive family history (154). This polymorphism represents a good example of susceptibility alleles, which are quite common in the population, but explains only a small part of the blood pressure variance in the overall population.

One possibility is that molecular variants of *AGT* might represent also a susceptible allele for pregnancy-induced hypertension, for which a familial tendency has been documented (155,156). Ward et al. found a significant association between the *AGT* 235T variant and preeclampsia in both white and Japanese samples (157). Using another strategy, analysis of the allelic inheritance of *AGT* repeat in 52 sibling pairs of preeclamptic sisters, Arnggrimsson et al. showed a significant linkage between *AGT* and preeclampsia in Icelandic and Scottish families (158). The association in Japanese women was confirmed in a larger case-control study involving 139

women with pregnancy-induced hypertension and 278 matched controls (159). However, other studies limited in their sample size found no indication of association or linkage between preeclampsia and *AGT* in white women (160–162). More recently, a significant increase of the T235 allele frequency in a large series of preeclamptic women of African origin identified on the island of Mauritius was found (163). Interestingly, nulligravid women homozygous for T235 have a reduced plasma volume during the follicular phase of the menstrual cycle than those bearing the MT or MM genotype (164).

The pathogenesis of preeclampsia is probably influenced by a variety of genetic (maternal and paternal) and nongenetic factors. Recent GWS studies have reported possible loci on chromosomes 4q and 2p (162,165,166). The gene coding for nitric oxide synthase (NOS) has also been linked to the pathology (160). The possible pathophysiologic relationship between *AGT* and pregnancy-induced hypertension may be due to both an increased expression of angiotensinogen in decidual arteries and decreased formation of high-molecular-mass angiotensinogen, an aggregate form of the protein that is particularly abundant during pregnancy (144,167). The M235T polymorphism was also found to be associated with increased response of plasma angiotensinogen to a 1-week exposure to ethinyl estradiol in normal volunteers (168). From all these studies, *AGT* appears to be involved in the determination of human familial hypertension and some forms of pregnancy-induced hypertension. However, its exact quantitative effect on blood pressure is unknown but might be weak and modulated by a variety of interacting loci and environmental factors, accounting for the negative results in some underpowered studies (169).

**52.3.1.4 The Angiotensin II Type 1 Receptor (OMIM \*106165).** Angiotensin II receptors, which mediate all the biologic and physiologic effects of the renin-angiotensin system, are also candidate genes for essential hypertension. The angiotensin II type 1 receptor (AT1R) subtype is a G-coupled receptor inserted into the plasma membrane of angiotensin II target cells, vascular smooth muscle cells, renal vasculature and mesangial cells, adrenal glands, and brain. The human gene (*AT1R*) has been cloned and is located on chromosome 3q21–3q25 (170,171).

In the first series of experiments, Jeunemaitre et al. looked for putative molecular variants in the coding region of the gene that would result in overactivation of the receptor. Such variants have been reported for other G-coupled seven transmembrane-domain receptors, such as the human thyrotropin and luteinizing hormone receptors, resulting in a constitutive activation or hyperresponsiveness of the receptors (172,173). In the case of hypertension, similar functional variants of angiotensin II receptors could theoretically lead to some forms of essential hypertension or to tumoral sporadic primary aldosteronism. However, no evidence of such mutations

in the coding region of AT1R was found in 60 probands of hypertensive families and in 20 cases of tumoral primary aldosteronism (174,175). There was no evidence of linkage between a microsatellite marker of AT1R and hypertension in a hypertensive sibpair study. However, an informative diallelic marker (A1166C) present in the 3' untranslated region of AT1R was found significantly more frequently in 206 hypertensive subjects than in 298 normotensive controls, suggesting that a variant of the AT1 receptor exerts a small effect on blood pressure (174). This specific polymorphism was significantly associated with hypertension in a Japanese woman during her first pregnancy (176).

Other polymorphisms have been described, especially at the promoter region of AT1R. However, none of these polymorphisms has shown evidence for association with hypertension in a large white population-based sample (177). Studies performed in Finland suggest linkage at the AT1R locus and association with the A1166C polymorphism (178,179). It is interesting to note that the A1166C polymorphism of AT1R has also been associated with aortic stiffness in essential hypertension, left ventricular mass, coronary vasoconstriction, different responses to Ang II in isolated human arteries, and myocardial infarction in interaction with the ACE I/D polymorphism (180–184). However, these associations have been disputed in other studies, and no relation was found between AT1R density in platelets and the A1166C genotype (146).

## 52.3.2 Sodium Channels

**52.3.2.1 Subunits of the Epithelial Sodium Channel.** Epithelial sodium channel (ENaC) is the rate-limiting step of Na<sup>+</sup> reabsorption by the kidney distal tubule. As discussed in Section 52.2.2.1, the presence of gain-of-function mutations in the genes coding for the  $\beta$ - and  $\gamma$ -ENaC subunits suggests the possibility of more subtle polymorphisms at those genes that might modify ENaC activity, especially in salt-sensitive patients or those with a low-renin profile. Several groups, therefore, have extended the screening for mutations in essential hypertension to  $\beta$ - and  $\gamma$ -ENaC. In a series of more than 400 hypertensive subjects, seven missense mutations were found at the gene coding for the  $\beta$ -ENaC subunit (SCNEB; 16p13–p12), almost all of them in patients of African descent (185). Whereas these variants led to no significant increase in Na<sup>+</sup> current after expression in *Xenopus* oocytes, data obtained in human B lymphocytes suggest that at least one of them (T594M) could have an effect on Na<sup>+</sup> reabsorption (186). In a case-control study involving black residents of London, Baker and associates found a significant increase of the 594M frequency in the 206 hypertensive patients (8.3%) compared to the normotensive subjects (2.1%), the statistical significance persisting after adjustment for sex and BMI (187). In the subset of patients in whom plasma

renin activity was measured, the T594M polymorphism was also associated with a low-renin profile, suggesting that it could raise blood pressure in affected people by increasing renal tubular sodium reabsorption. However, the impact of this polymorphism is still debated.

Several polymorphisms have also been detected in  $\gamma$ -ENaC (SCNNIG; 16p13–p12) including four neutral polymorphisms—three in the third exon of the gene (T387C, T474C, C549T) and one in the last exon (C1990G) (188). These four variants had similar frequencies in 453 hypertensive and 245 normotensive white subjects as well as in patients with a low-renin profile. Two rare mutations were also found in three hypertensive subjects, 594insP and R631H, that produced no significant increase in Na<sup>+</sup> current in *Xenopus* oocytes. Results obtained by other groups confirm that this subunit is infrequently involved in essential hypertension (189). The analysis of  $\gamma$ -ENaC showed an interesting missense polymorphism (W493R) located in the extracellular loop of the subunit and in a rather well-conserved sequence not far from the amino acids responsible for the sensitivity to amiloride. However, in whites, this polymorphism was found at a similar allele frequency in hypertensive and normotensive individuals and did not change the amiloride-sensitive current when expressed in *Xenopus* oocytes (190). Other polymorphisms (G442V at  $\beta$ -ENaC and T663A at  $\alpha$ -ENaC) have been shown to be associated with changes in the aldosterone:potassium ratio in urine and with essential hypertension (191). It is also interesting to note that a sibpair linkage study performed on 286 white Australian families showed significant linkage between SBP and microsatellites at chromosome 16p12, located in the vicinity of the genes encoding the  $\beta$  and  $\gamma$  subunits of ENaC (192).

**52.3.2.2 Guanine Nucleotide-Binding Protein (OMIM \*139130).** Several studies have suggested increased activity of the sodium-proton exchanger in about 50% of subjects with essential hypertension. Increased ion transport activity has also been found in immortalized lymphoblasts and in fibroblasts from hypertensive subjects that might be due to altered intercellular signal transduction and enhanced activation of pertussis toxin-sensitive G proteins (193). The heterotrimeric G proteins are formed by the assembly of several subunits ( $\alpha$ ,  $\beta$ , and  $\gamma$ ). After having excluded mutations of several of these subunits, Siffert et al. found a very interesting genetic polymorphism (C825T) in exon 10 of the gene coding for the  $\beta_3$  subunit (GNB3; 12p13) (194). This polymorphism is not a missense mutation but favors the use of an alternative splicing of exon 9 of the gene and thus the expression of a protein with a deletion of 41 amino acids. The expression of the deleted protein in insect cells showed that it was functional but that it presents an enhanced reactivity to pharmacologic activators. Finally, in this pioneering study, the 825T allele was more frequent in 426 hypertensives (0.31) than in 427 controls (0.25), suggesting its role as a susceptibility factor for

essential hypertension. However, this association with essential hypertension has been controversial.

In a population-based study at Augsburg (Germany) selected from the MONICA survey, the C825T polymorphism showed a weak, albeit significant, association with diastolic blood pressure (195). Interestingly, plasma renin levels were lower in patients bearing the 825T allele, suggesting that it might be associated with a low-renin profile. An association study performed in 110 Australian white hypertensives, each of whom was the offspring of two hypertensive parents, and 189 controls whose parents were both normotensive beyond the age of 50 years, found a significant difference in the 825T allele frequency, supporting a role for this variant (196). In contrast, Brand et al. analyzed the GNB3 variant in two large case-control studies selected for essential hypertension (PEGASE study) and myocardial infarction (ECTIM study) (197). The odds ratios for hypertension and myocardial infarction associated with T-allele carrying were 1.23 (95% CI, 0.94–1.62;  $P=0.13$ ) and 1.11 (95% CI, 0.88–1.39;  $P=0.37$ ), respectively. There was no association of the GNB3 polymorphism with early onset of hypertension, familial history of hypertension, or blood pressure. In a German case-control study involving 479 hypertensives and 1000 gender- and age-matched controls, the 825T allele was associated with an OR of 1.5 (95% CI, 1.1–2.2) versus non-T carriers for the presence of hypertension (198). However, in both the whole group and the untreated group, blood pressure levels were virtually identical between the genotypic groups. In a study performed in 447 Indians of the Oji-Cree tribe in Canada, the frequency of the 825T allele was 0.50, much greater than those usually observed in whites (199). Surprisingly, the 825T allele was associated with a lower mean SBP (CC, 126.7 mmHg; CT, 123.5 mmHg; TT, 119.6 mmHg;  $P<0.05$ ) and was not associated with significant difference in diastolic blood pressure. A Japanese study seems to confirm these negative results (200). The frequency of the 825T allele was very similar (0.49) in 718 subjects with confirmed essential hypertension, 191 with borderline hypertension and 515 controls, all from the Tokyo area.

The hypothesis of a genetic polymorphism of the GNB3 subunit favoring high blood pressure is attractive because of its possible ubiquitous effect, especially on the vascular tone on the renal sodium handling. In this regard, the measurement of this polymorphism in 197 blacks and 190 non-Hispanic whites who underwent monotherapy with hydrochlorothiazide for 4 weeks showed that 825TT homozygotes had greater response of both diastolic and SBP than the CC homozygotes (201).

### 52.3.3 Other Candidate Genes

Many other genes can be considered as excellent candidates for essential hypertension. A list of more than

100 genes that may act directly or indirectly on blood pressure is easily established (Table 52-1). Among them are genes coding for proteins of the adrenergic systems (dopamine receptors,  $\alpha$ - and  $\beta$ -adrenergic receptors in particular), for proteins involved in salt–water homeostasis (natriuretic peptides and their receptors, subunits of the epithelial sodium channel, renal transporters, kallikrein–kinin system, etc.), for proteins involved in the hormonal regulation of blood pressure (enzymes and receptors of the mineralo- and glucocorticoid pathways), and for proteins involved in the structure and/or the regulation of vascular tone (endothelins and their receptors in particular).

It is, of course, not possible to summarize here the studies that have been performed for all these candidate genes, except to note that none of them has been firmly established as bearing polymorphisms strongly favoring changes in blood pressure. For example, the gene coding for the endothelial cell NOS was very attractive since nitric oxide plays an important role in regulating blood flow and pressure. Several reports have suggested that hypertensive subjects have a blunted endothelium-dependent vasodilation that might be secondary to decreased nitric oxide production. However, linkage and case-control studies performed in French hypertensive and normotensive subjects failed to show association or linkage with essential hypertension, suggesting that common variants of this isoform of NOS are not involved in common hypertension (202). Similar negative results were obtained in humans for the acyl-CoA synthetase medium chain family (ACSM3 or SA; OMIM \*145505) locus, which was linked to blood pressure levels in several crosses involving different strains of genetically hypertensive rats (203,204).

The gene coding for aldosterone synthase (CYP11B2; OMIM \*124080) is also an attractive candidate (205). It has been tested for its possible association with essential hypertension and primary aldosteronism (206–209). A polymorphism in the promoter region of the gene (C-344T) is located at a steroidogenic transcription factor (SF-1 binding site) and could play a role in the expression of the gene. Despite the fact that the Ang II,  $K^+$ , and cyclic AMP signaling pathways utilize in vitro a CRE-like *cis*-element and another SF-1 binding site that is located closer to the transcription start to regulate human CYP11B2 expression, the C-344T polymorphism has been associated with variations in plasma aldosterone, suggesting that it could favor sodium retention and high blood pressure (206,210,211). Contradictory results have been obtained according to the populations and the biochemical and clinical parameters studied (212–214).

The group headed by G. Bianchi in Milan has extensively studied the possible role of  $\alpha$ - and  $\beta$ -adducin genes in rat and human hypertension (215). Adducin is a cytoskeletal protein that favors the association between spectrin and actin, but it can also directly interact with actin.

**TABLE 52-1** Some Loci Associated with Abnormal Regulation of Blood Pressure or Hypertension Determined by Large-Scale GWAS

Ethnicity	Phenotypes	Locus	P value	Nearest gene
Asian	SBP	12-88,584,717	$9.1 \times 10^{-7}$	ATPB1
Asian	DBP	12-88,584,719	$1.2 \times 10^{-6}$	
Americans of African descent	SBP	2-190,446,083	$2.1 \times 10^{-11}$	<i>PMS1</i>
		6-16,031,005	$3.4 \times 10^{-9}$	MYLIP
		8-102,026,053	$1.6 \times 10^{-8}$	<i>YWHAZ</i>
		11-9,388,666	$4.8 \times 10^{-8}$	<i>IPO7</i>
		14-91,877,083	$1.5 \times 10^{-8}$	<i>SLC24A4</i>

	DBP	15-72,912,698	$8.1 \times 10^{-7}$	<i>CPLX3</i>

Phenotypes: DBP=diastolic blood pressure; SBP=systolic blood pressure; HTN = hypertension.

Locus: chromosome position.

Adapted from Ehret, G. B. Genome-Wide Association Studies: Contribution of Genomics to Understanding Blood Pressure and Essential Hypertension. *Curr. Hypertens. Rep.* 2010, 12 (1), 17–25.

Thus, it might be involved in cellular signal transduction and interact with membrane cytoskeletal proteins that affect ion transport across the cell membrane. Adducin is a heterodimeric protein that is composed of three subunits,  $\alpha$ ,  $\beta$ , and  $\gamma$ . Each subunit is composed of two distinct domains: an N-terminal globular hydrophobic domain and a C-terminal tail responsible for its interaction with actin and spectrin. The  $\alpha$ -adducin gene (*ADD1*) is located at human chromosome 4p16.3 and was identified because of its proximity to the gene responsible for Huntington disease. The  $\alpha$ -adducin gene is widely expressed, but is predominantly expressed in brain and kidney tissue. The  $\beta$ -adducin gene is 50% identical, and is expressed as different tissue-specific isoforms. Thus, there are physiologic quantitative and qualitative differences in assembly of these subunits according to the tissue in which they are expressed.

Bianchi et al. hypothesized that variations in adducin could lead to variations in the activity of ion transporters or channels, especially the  $\text{Na}^+\text{-K}^+\text{-Cl}^-$  cotransporter in the thick ascending limb and  $\text{Na}^+\text{-K}^+\text{-ATPase}$  all along the renal tubule, thus leading to increased salt reabsorption and hypertension. The Milan hypertensive strain (MHS) of rat has characteristics that suggest a renal abnormality of sodium handling: increased glomerular filtration rate during the first weeks of life, low-renin

status, and increased sensitivity to furosemide compared to the Milan normotensive strain (MNS) (215). Differences in the amino acid sequence of the adducin genes between the MHS and MNS strains could explain a significant part of the blood pressure difference between these two strains. Indeed, two amino acid changes were found in the  $\alpha$ -(F316Y) and  $\beta$ -(Q529R) adducin genes. The transfection of wild or mutant subunits in renal epithelial cells showed that these mutations induce an increased activity of the  $\text{Na}^+\text{-K}^+$  pump, thus establishing a pathophysiologic link with increased renal sodium handling and high blood pressure.

In humans, several recently concordant studies establish a relation between the  $\alpha$ -adducin gene and salt sensitivity and blood pressure, even though its effect is probably mild at the population level. In a study involving French and Italian hypertensive sibpairs, significant linkage was found between several markers surrounding the  $\alpha$ -adducin locus and essential hypertension (216). A positive association was also found when the authors compared the genotype frequencies of the G460W polymorphism of the  $\alpha$ -subunit of the adducin gene in 190 hypertensive patients and 126 controls. The blood pressure response to the chronic administration of hydrochlorothiazide was also significantly more important in subjects bearing the 460W allele, suggesting that this

variant could predispose to salt sensitivity and to hypertension. Since then, other studies have been performed with conflicting results. The association with low-renin status was recently confirmed in a multicenter international study investigating intermediate phenotypes in hypertension (217). Allayee et al. found no association between ADD1 polymorphisms and SBP in Dutch subjects (28). Determination of the exact importance of the adducin locus in human hypertension will probably require large-scale studies as well as a search for interaction with other genes and sodium content of the diet.

## 52.4 GENOME-WIDE ASSOCIATION STUDIES

GWAS were undertaken with the primary aim of identifying novel genetic loci associated with variation in risk of clinical diseases, subclinical disease, and levels of risk factors. Taking into account the major advances accomplished in recent years on the genetic and physical map of the human genome, this approach has become a major strategy to identify major loci implicated in complex traits. Once the regions of interest have been identified, a systematic analysis of their genes is undertaken based on their possible function (i.e. the positional candidate gene approach) (218). Because it does not make any *a priori* assumption as to the genes to identify, this strategy is designed for discovering new pathways involved in blood pressure regulation.

However, there are strong statistical limits to this approach that have been well delineated (219–222). Among them are the problem of power to identify loci that have only a small influence on blood pressure level; the requirement of nonparametric methods, necessitating the use of hundreds of sibpairs and/or particular study designs such as discordant sibpairs; the necessity of adjustment of the statistical significance for multiple testing, which might prevent the identification of genes with mild effects on the trait; the requirement of replication of any positive result in another sample with the same characteristics using either the same design or a complementary approach such as family-based association studies or case-control studies; the low power of replication for loci with only a small blood pressure effect; the possible heterogeneity of genes causing essential hypertension according to the ethnic background; and the confounding factors such as obesity or associated diseases such as dyslipidemia and diabetes. Finally, one must be aware that GWAS, at least in the initial stage, does not take into account the interaction among genes and between genes and environment, which are the mechanisms at work at the phenotypic level. Thus, negative results can be obtained for a locus with a true biologic and clinical effect that would be detected only if analyzed in combination with other loci or with environment. Despite these limits, several GWAS have produced interesting results. A nonexhaustive summary of these studies is presented in this section and in Table 52-2.

**TABLE 52-2** Some Mendelian and Mitochondrial Conditions Associated with Hypertension

Phenotype	OMIM No.	Locus	Gene
Apparent mineralocorticoid excess	218030	16q22.1	HSD11B2
Early-onset hypertension	605115	4q31.23	NR3C2
Glucocorticoid remediable aldosteronism	103900	8q21	CYP11B1
Hypomagnesemia, hypertension, hypercholesterolemia	500005	Mitochondrial	tRNA Ile
IgA nephropathy	106150	1q42.2	AGT

Williams–Beuren syndrome	194050	7q11.23	

One of the first GWAS to be published was that performed by the group of Boerwinkle based on the Family Heart Program in Rochester, Minnesota, that included 3974 subjects from 583 families. The first study was performed based on the selection of 69 sibling pairs highly discordant for their blood pressure level (above the eightieth percentile or below the twentieth percentile) (223). Four genomic regions (2p22, 5q33, 6q23, 15q25) were suggested to be linked with SBP. In a second study, the authors analyzed the candidate genes contained in the most promising region (5q33); among them, the dopaminergic receptor type 1A, the  $\alpha$ 1B-adrenergic receptor, and the  $\beta$ 2-adrenergic receptor (224). For each of those, an extensive search for polymorphisms was performed followed by genotyping the study population. Most results

**TABLE 52-3** Some Mendelian Conditions Associated with Hypotension

Phenotype	OMIM No.	Locus	Gene

did not show any consistent association between these polymorphisms and blood pressure. The polymorphism (Arg16Gly) of the  $\beta$ 2-adrenergic receptor appeared the most interesting because of its association with significant, although minor, changes (2–3 mmHg) of SBP. Another study was performed in England on 119 white families selected based on the presence of at least three hypertensive subjects in the same sibship (147). The genome scan used 262 markers and identified a suggestive region on chromosome 11q. However, the analysis of 124 additional families did not confirm that location. A statistical simulation confirmed the genetic complexity of essential hypertension, with a multipoint exclusion-linkage analysis showing that at least three genetic loci were necessary to explain the familial aggregation of the trait.

The Amish population seems ideal for genetic studies looking at blood pressure because of both the large size of the families and the homogeneous environment compared with outbred populations. The study reported by Hsueh and colleagues involved 694 subjects from 28 families, each containing 3–69 individuals (225). A total of 357 microsatellite markers have been genotyped in 436 parent–siblings couples, 1326 sibling pairs, 1342 relations between first-degree relatives, and 1311 relations between first cousins. In these families, heritability was 0.23 for systolic pressure and 0.29 for diastolic pressure, estimations similar to previous observations. The only

region that was linked without ambiguity to the trait was located in 2q31–34, with LOD scores of 1.64 for systolic and of 3.36 for diastolic blood pressure. The GWAS was performed on 1702 subjects from 332 families selected from the Framingham survey (226). For each individual, blood pressure was measured at least three times over a period of at least 10 years. The quantitative trait analyzed was the blood pressure averaged on this duration and adjusted for age and BMI. A 10-cM genome scan was performed that allowed the analysis of the following relative pairs: 1545 sibling pairs, 933 parent–offspring pairs, 742 cousin pairs, and 468 pairs of other first-degree relatives. The statistical analysis showed only one region of interest—chromosome 9—for diastolic blood pressure. For SBP, a suggestion of linkage was found for several regions on chromosomes 5, 10, and 17. On chromosome 17, two regions were suggested, with the one located on 17q12–21 giving the most promising multipoint LOD score (4.7).

This chromosome 17 region corresponds with what was also found by Julier et al. (126). In this study involving French hypertensive sibpairs, French diabetic pairs with hypertension, and U.K. families, significant linkage and association were found using markers of the same region that contains the ACE locus at its telomeric end. However, no particular gene has yet been proven as the one responsible for this statistical association. Other arguments make this a region of interest. First, it corresponds to the chromosome 10 region in the rat genome, a region that has been shown by two groups to contain a major locus, explaining up to 20% of the blood pressure variance in the stroke-prone spontaneously hypertensive rat compared to its normotensive counterpart, the WKY rat (115,116). Second, it is also a region containing one of the genes responsible for pseudohypoaldosteronism (PHA2B), an autosomal dominant hypertensive condition associated with hyperkalemia despite normal glomerular function (227). Finally, a missense polymorphism (Gly40Ser) at the glucagon receptor gene located at 17q25 has been associated with hypertension with an allele frequency of 0.08 in a limited set of white hypertensives who have two hypertensive parents compared to only 0.01 in normotensive controls (228). This polymorphism was not significantly associated with hypertension in the overall sample of 741 French hypertensive subjects compared to 412 controls (229) (Table 52-3).

The Finnish Twin Cohort Study has also been used for a GWAS of blood pressure (179). The strategy was to study a limited number of pairs with an early-onset phenotype (mean age at discovery, 38.3 years) and to diminish the effect of possible confounding factors (at least one sib with BMI < 27 kg/m<sup>2</sup>, exclusion of diabetes). Only 47 sibpairs were studied, comprising 36 dizygotic twins and 11 nontwin siblings, in the first stage of the analysis. In stage 2, genotyping was focused on the regions of suggestive linkage, with the addition of all available family members of the 47 probands (total of 138 subjects).

Despite these relatively small numbers, several regions gave a maximum likelihood score  $>1.5$  (1q, 2q, 22q, and Xp). The most significant result was obtained on chromosome 3q21–25 (maximum likelihood score = 3.38 on the entire sample). This region contains AT1R, and the stronger result was obtained with the intragenic CA repeat at this locus. Analysis of candidate genes in a German population, using blood pressure as a quantitative trait, also suggested linkage with AT1R (230). GWAS was also performed in 125 random and 81 obese families participating in the Québec Family Study (231). Multiple linkage regions were suggested for SBP, especially on chromosomes 1p, 2p, 5p, 7q, 8q, and 19p. One of the main interests of this study was to show the importance of gene–gene or gene–environment interactions, suggested by the fact that most of the regions that were suggested in lean families did not show any linkage when analyzed in families in which one or more members had a BMI  $>32$  kg/m<sup>2</sup>.

In order to increase the sample size and to replicate findings, multiple large population-based cohort studies collaborated. One of these endeavors, the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium gathered genome-wide data for about 38,000 individuals, with large numbers of detailed health-related phenotypes measured in similar ways (232). The CHARGE blood pressure group with a joint meta-analysis with the Global BPgen Consortium identified four SNPs associated with SBP in ATP2B1, CYP17A1, PLEKHA7, SH2B3, six SNPs associated with diastolic blood pressure in ATP2B1, CACNB2, CSK-ULK3, SH2B3, TBX3-TBX5, ULK4, and one SNP associated with hypertension in ATP2B1 (233).

In the largest GWAS to date with over 200,000 individuals of European descent, the International Consortium for Blood Pressure Genome-Wide Association Studies identified 16 novel loci, including six loci containing genes previously known to regulate blood pressure (GUCY1A3-GUCY1B3, NPR3-C5orf23, ADM, FURIN-FES, GOSR2, GNAS-EDN3) (234). It was concluded that multiple common genetic variants contribute to interindividual BP variation in people of European and non-European ancestry. Even though the effect sizes of risk alleles were small, 1/0.5 mmHg, the aggregate effect on BP appears clinically relevant (234). It is interesting to note that one of the loci identified contains a gene, CYP17A1, known to be responsible for the Mendelian form of hypertension—congenital adrenal hyperplasia. Another locus contains ADM, which encodes adrenomedullin, which has natriuretic, vasodilatory and BP-lowering properties. Other loci identified include GNAS, which encodes a subunit of G-protein, mediating signal transduction at adrenergic receptors, and SLC4A7, which encodes a sodium/bicarbonate cotransporter.

With the goal of discovery of new variations associated with traits using a candidate gene approach and the discovery of new variants using the genome-wide

association mapping approach, the Candidate Gene Association Resource (CARE) was developed to perform cross-cohort analysis of genetic variation in cardiovascular, pulmonary, and other traits, comprising over 40,000 participants in nine community-based cohorts (235). In 8090 African-Americans the CARE project identified and replicated 17 loci previously associated with coronary heart disease or its risk factors including high blood pressure in Caucasians, including CDKN2A/CDKN2B and FADS1–3, PLTP, LPL and ABCA1 (236). Admixture mapping analysis for SBP and diastolic blood pressure was also employed to detect disease variants with substantial allele frequency differences followed by trait-marker association analysis in ancestral populations in the CARE consortium. It was found that in 6303 unrelated African-Americans and subsequently replicated in 11,882 independent of African-American subjects, that a novel variant on chromosome 5 between the SUB1 and NPR3 genes was associated with both SBP and DBP (237). Using candidate gene SNP data on a 50K cardiovascular gene-centric array, the CARE consortium found an association for SBP near SLC25A42 and for DBP near HLA-B (238). Previously reported European-American blood pressure SNPs were also replicated in this African-American samples, including SH2B3, TBX3-TBX5 and CSK-ULK3 (238). It is also of note that genome-wide studies undertaken to study metabolic syndrome has identified SNPs that contribute to variation in SBP, further demonstrating the complicated polygenic nature of this common disease (239).

## ACKNOWLEDGMENT

This work was supported by grants from the National Institutes of Health and Cedars-Sinai Medical Center.

### Biographies

**Frank S Ong MD**, Dr Ong graduated with high honors from the University of Southern California in Gerontology (BS), Biological Sciences (BA) and Medicine (MD). He then served as resident physician in the Department of Family Medicine at Geffen School of Medicine, UCLA. He completed a research fellowship in genetics of hypertension at Cedars-Sinai Medical Center and a clinical fellowship in molecular genetics at UCLA. Dr Ong is now the faculty of Biomedical Sciences at Cedars-Sinai Medical Center. He has served as a peer-reviewer for *Hypertension*, *Journal of the American College of Cardiology*, *The Pharmacogenomics Journal*, *Pharmacogenetics and Genomics*, and *PLoS ONE*. He is also a Western Regional Councilor and Institutional Representative for the American Federation of Medical Research. He has received numerous awards, including American Heart Association Kidney Council New Investigator Award for High Blood Pressure Research, Western Society for Clinical Investigation Award, Cedars-Sinai Medical Center Sports Spectacular Endowed Fellowship Award and the American Federation of Medical Research Henry Christian Award. He has been funded by the NIH for work on the angiotensin-converting enzyme and injury. He is also active in several population genetics consortia focusing on the genetics of blood pressure regulation and pharmacogenetics. He enjoys playing the violin and hiking.

**Kenneth E Bernstein MD**, Dr Bernstein is currently a Professor of Biomedical Sciences and Pathology and Laboratory Medicine at Cedars-Sinai Medical Center. He began his research training as a postdoctoral Fellow in the Laboratory of Immunology, NIH, Bethesda, MD. In 1987, he relocated to Emory University where he remained until 2008, when he came to Cedars-Sinai. Bernstein has studied ACE, angiotensin II, and the renin-angiotensin system for more than 25 years and published over 145 papers describing original findings. He has made many important contributions including cloning the gene encoding the angiotensin converting enzyme and angiotensin II AT1 receptor, identifying the testis ACE promoter, elucidating novel kinase signaling by the AT1 receptor (Jak/STAT and Src signaling), and most recently, using targeted homologous recombination to create several novel mouse models of ACE expression. Dr Bernstein received the AHA's Novartis Prize for Hypertension Research in 2005 and the AHA's Basic Science Prize in 2007, only the fourth person to win both these international awards.

## Preeclampsia

*Anthony R Gregg*

Department of Obstetrics and Gynecology, University of Florida, College of Medicine,  
Gainesville, FL, USA

### 53.1 INTRODUCTION

Abnormalities of blood pressure regulation can precede, arise during, or appear for the first time in the puerperium of pregnancy. The terminology used to describe these conditions has varied across time and the definitions applied to many of these terms have also changed. These fluctuations confound the interpretation of aggregate data from the literature. This includes the data that address the epidemiology, etiology and management of these conditions. Preeclampsia is a hypertensive disorder of pregnancy that is associated with proteinuria. The prevalence varies across geographic regions (115) and racial/ethnic groups (97). In one prospective cohort study, the relative risk for preeclampsia in black women was 2.4 (95% confidence interval 1.1–5.6) compared to white women (81). Socioeconomic factors also appear to influence the general demographics for this condition. The adjusted odds ratio for preeclampsia was 4.0 (95% confidence interval 1.1–14.0) for persons who receive no prenatal care (60). Data extrapolated from renal biopsies suggests that parity is important, with a greater risk of preeclampsia among nulliparous women. Furthermore, underlying renal disease is an important covariable among multiparous women who display the condition (105). In a review that compared the onset of preeclampsia in mothers carrying twin vs singleton pregnancies, the relative risk of developing preeclampsia was increased among those carrying twins (2.8–4.4) (85). In addition, preexisting medical conditions, wherein hypertension and renal disease may be observed simultaneously (e.g. diabetes, chronic hypertension, autoimmune disorders), increase the risk of developing preeclampsia (111). Generally speaking, preeclampsia occurs in 1–6% of all pregnancies with much higher numbers (10–20%) reported for nulliparous women (115,125). Of course, accepting any statement on prevalence is tempered by varied nomenclature used to describe diseases characterized by hypertension during pregnancy and the specific definitions used to define preeclampsia. In the United States, preeclampsia ranks among the top three causes of maternal death (15.7%, 1.8/100,000 live births) compared to embolism (19.6%,

2.3/100,000) and hemorrhage (17.2%, 2.0/100,000) (29). Preeclampsia also takes a toll on fetal/neonatal well-being. Mothers with preeclampsia are more likely to deliver preterm neonates that are small for gestational age (i.e. fetuses have intrauterine growth restricted). This leads to higher perinatal morbidity and mortality rates.

Preeclampsia is a quantitative trait disorder that is likely to be polygenic and result from multiple factors, some genetic and some environmental. Proteins and the genes that encode them are emerging as are the interactions between environmental factors and these proteins. Whether the aggregate of these has their greatest impact at the maternal–placental interface, within the maternal or fetal compartments, or are in fact playing their roles in various compartments depending on the gestational age of the pregnancy remains to be clarified. Independent of our ability to understand the proteins and interactions that give rise to preeclampsia, one thing seems certain: preeclampsia has a heritable basis.

### 53.2 CLASSIFICATION

Before 2000, consensus regarding the nomenclature for the disorders characterized by hypertension during pregnancy had been lacking. More recently, several national (e.g. American College of Obstetricians and Gynecologists) and international entities (e.g. International Society for the Study of Hypertension in Pregnancy) have adopted the nomenclature put forth by the National Institutes of Health/Working Group Report on High Blood Pressure in Pregnancy 2000 (Table 53-1) (125). More devastating than the problem of delay in adopting an agreed-upon nomenclature for disorders of hypertension during pregnancy, the criteria used to define preeclampsia have been changed on multiple occasions over time. Currently, there is not a single agreed-upon definition (125). The unifying characteristics among those proposed are hypertension and proteinuria; after this, there is a great deal of divergence—some subtle and some glaring.

**TABLE 53-1 Classification Scheme for Conditions Characterized by Hypertension during Pregnancy**

	Pre-eclampsia	Chronic Hypertension with Superimposed Preeclampsia	Chronic Hypertension	Gestational Hypertension	Transient Hypertension	Pregnancy Induced Hypertension	Unclassified
NIH/NICHD (126)	X	X	X	X			
NIH/NICHD (115)	X	X	X		X		
ACOG (2)			X			X	
ACOG (67)	X	X	X	X			X
Canadian Hypertension Society (108)		X	X	X			X
WHO (152)	X		X				

### 53.2.1 Hypertension

Blood pressure is a quantitative trait (see Chapters 76 and 77). The threshold values for systolic (140 mmHg) and diastolic (90 mmHg) blood pressure used to discriminate between normotensive and hypertensive measures were first adopted in 1952 (146). These values apply to pregnant women independent of their age. In conflict with these values are published norms for teenage girls. In this subgroup of patients, blood pressure values that exceed the mid-130 mmHg systolic or the mid-80 mmHg diastolic are above the ninety-fifth percentile value (126). Yet pregnant teens do not meet current blood pressure criteria for preeclampsia until either the systolic or diastolic values meet or exceed 140 mmHg or 90 mmHg, respectively. This represents the most obvious example that for quantitative disorders (e.g. hypertension) that are defined by threshold values, age-specific normative data are required. There are also racial differences with respect to blood pressure changes across pregnancy (97). In a recent report, fifth and ninety-fifth percentile confidence intervals were generated for blood pressure across pregnancy (83). Importantly, this was completed for a defined population, Mexican-Hispanics. An additional consideration includes variation in techniques used to measure blood pressure. The National Institutes of Health/Working Group Report on High Blood Pressure in Pregnancy 2000 has adopted Korotkoff sound 5 for use in determining diastolic blood pressure. This report requires that blood pressure meet or exceed 140 mmHg systolic or 90 mmHg diastolic after 20 weeks of gestation. Furthermore, this threshold must have been reached on at least two occasions (125).

### 53.2.2 Proteinuria

Proteinuria in pregnancy is most often determined using a 24 h collection, and protein values are expressed per unit time (24 h). Values exceeding 300 mg are considered pathologic if they appear for the first time after 20 weeks gestation. This defining feature varies little among groups that have demonstrated an interest in

setting disease defining thresholds for this quantitative trait. More recently, attention has been paid to indentifying patients who might not require a 24 h urine collection. The suggestion has been made that a specific protein/creatinine (P/C) ratio threshold might establish those that are more likely to have a negative 24 h urine collection, thus sparing the health care system and patients cost and inconvenience, respectively. In a review of 10 publications (1994–2004) reporting on the use of a random urine calculation of the P/C ratio in pregnancy, there was a strong correlation between this and a formal 24 h urine calculation of total protein (122). These authors recommend obtaining a formal 24 h urine collection when the P/C ratio exceeds a predetermined cutoff. The International Society for the Study of Hypertension in Pregnancy (ISSHP) has endorsed a P/C ratio cutoff  $\geq 30$  mg/mmol as equivalent to a 24 h specimen (22).

In conclusion, preeclampsia is a quantitative trait disorder that is identified only in females during a specific lifetime event—pregnancy. Furthermore, this condition requires defined thresholds for elevated blood pressure and renal dysfunction, in the form of proteinuria, to establish the disease. Unfortunately, these criteria may not be generalizable to all pregnant patients (e.g. teenagers, patients with underlying renal disease).

### 53.2.3 Other Features

Once the diagnosis of preeclampsia is established, management decisions are based upon clinical features that include the gestational age of the fetus, degree of blood pressure elevation at the time of diagnosis, and the response of blood pressure to therapeutic interventions (e.g. bed rest, medication). Severe disease often results in the need for preterm delivery. Severe disease is defined by blood pressure, quantitative measure of urine protein, platelet count, and serum chemistries. Severe disease is also considered to be present when tests of fetal well-being demonstrate compromise and there are specific maternal signs and symptoms (Table 53-2) (58). Although protein in a 24 h urine collection is used to define severe disease,

**TABLE 53-2** Criteria Used to Establish Severe Preeclampsia

Severe blood pressure elevation
Elevated liver function studies
Low platelet count (100,000)
Eclampsia
Persistent maternal headache
Scotomata/blurred vision
Proteinuria ( $\geq 5$ g/24 h) and at least 34 weeks' gestation
Nonreassuring tests of fetal well-being
Oligohydramnios
Fetal growth restriction
Placental abruption

recent data suggests that if this is the only criterion of severe disease, the pregnancy can be allowed to continue until 32–34 weeks' gestation (35,132). Patients with preeclampsia do not follow a defined disease course. Severe disease is associated with a greater prevalence of maternal and fetal morbidity and mortality (98,137,138). For this reason, severe disease often results in preterm delivery and its sequelae.

### 53.2.4 Future Reproduction and Health Implications

Genetic counseling may be desired by patients who experienced preeclampsia in a previous pregnancy. Generally speaking, severity of disease in the index case influences recurrence in a subsequent pregnancy. Numerous clinical studies describe the recurrence risk of preeclampsia in a subsequent pregnancy. Recurrence estimates for preeclampsia range from 17.9% up to 55% if the index pregnancy was complicated by early severe preeclampsia with hemolysis, elevated liver enzymes and thrombocytopenia, or eclampsia (Table 53-3) (28,66,136). Since the risk of recurrent preterm delivery is a primary concern voiced by patients presenting for counseling on recurrence risk, a perspective on this risk can be helpful. A recent report of 334 patients delivered before 34 weeks because of a hypertensive disorder of pregnancy identified that 64% of patients refrained from

pregnancy. Of the remaining, 211 had a subsequent pregnancy, 17% had a recurrent preterm (<34 weeks) delivery due to a complication of hypertension and 14% delivered between 34 and 37 weeks. Of those delivering after 37 weeks, a minority had an uneventful pregnancy course (89).

The estimated incidence of chronic hypertension following a pregnancy complicated by preeclampsia has ranged from 0% to 78% with a mean of 23.8% (30,46,136). Long-term follow-up studies show that a higher proportion of eclamptic and preeclamptic women have developed chronic hypertension within 10 years of the index pregnancy (4.4%) compared with normotensive women (1.5%). The cumulative risk increased more with age in the eclamptic and preeclamptic group. In women observed for more than 10 years, the proportion was 51% compared with 14% in the normotensive group (136). Gestational age at first detection of high blood pressure seemed to be an important risk factor. Women with onset of high blood pressure before 31 weeks had a 2.3 times higher risk of developing chronic hypertension than those with later onset disease. Therefore, women who develop preeclampsia early in pregnancy are more likely to have the complications of hypertension and proteinuria in more than one pregnancy (recurrent preeclampsia), and those who develop preeclampsia for the first time in their second or later pregnancy are at risk of developing chronic hypertension. Although some still debate whether women with preeclampsia or transient hypertension have an increase risk of future hypertension compared to women without prior preeclampsia, the literature leaves little room for disagreement (4,93,133).

One way to measure whether the preeclampsia syndrome is a risk factor for future cardiovascular disorders is to determine the proportion of women who develop hypertensive complications or die from such complications. A significant increase in mortality rate has been observed in women (black and white) classified as parous at the time of the index pregnancy. The death rate was also significantly higher in black primigravid women but not in primigravid white women. The majority of the deaths (82%) were due to hypertensive cardiovascular complications, which was over three times the rate in

**TABLE 53-3** The Recurrence Risk of Severe Preeclampsia or the Risk of Chronic Hypertension When the Index Pregnancy was Complicated by Severe Preeclampsia

Index Pregnancy	Complicated by Early-Onset, Severe Preeclampsia (HELLP) Syndrome, or Eclampsia (28,66,136)	Early-Onset Preeclampsia (Delivery <34 Weeks) (89)	Eclampsia or Preeclampsia (136)
<b>Future Pregnancy</b>			
Overall recurrence	17.9–55%		
Complication requiring delivery <34 weeks		17%	
Chronic Hypertension with 10 years			4.4%
Chronic Hypertension greater than 10 years later			51%

women without pregnancy-related hypertension. Nearly half of this mortality was secondary to cerebral hemorrhage. Women with recurrent preeclampsia syndrome were also at high risk of early death from cardiac disease (31). This has been the case in the Icelandic population as well, where the death rate among women with previous hypertensive complications in pregnancy was significantly higher than expected. About 55% of the excess deaths were attributed to ischemic heart disease. An association with the severity of the pregnancy disease and the risk of developing ischemic heart disease later in life was also noted (72). The clinical symptoms at the time of pregnancy do not allow differentiation between those who are destined to develop chronic hypertension or heart disease in later life and those who will not do so. The same general advice on preventive measures to promote a healthy lifestyle must be targeted to all those at potential risk, at least until it becomes possible to separate subgroups at definite risk for subsequent cardiovascular disease.

### 53.3 PATHOLOGIC AND MOLECULAR BASIS

The pathogenesis of preeclampsia is not well understood. However, trophoblast invasion may hold the key. In normal pregnancy, there are two primary trophoblast invasion processes. One takes place as the trophoblast of the anchoring villi invades the decidua and the other centers on trophoblast invasion of the spiral arteries. If either of these processes become dysregulated poor placentation and a successful pregnancy outcome has the potential to be compromised. Research suggests that cytokine production by immune-regulatory cells, a hypoxic microenvironment within the decidua, abnormal immune recognition at the maternal-fetal interface, circulating “toxins” as a cause of endothelial dysfunction and altered vascular smooth muscle responses during pregnancy are probably the contributors to the hypertension-associated conditions of pregnancy, and more specifically, preeclampsia. It is unlikely that one of these alone determines the pathophysiologic events leading to preeclampsia. Since preeclampsia is a condition defined by quantitative traits, it is likely that perturbations in several genes, biologic pathways, and tissues lead to the aberrant blood pressure regulation and proteinuria that define this disease. Placental implantation represents a logical starting point to explore the pathogenesis of preeclampsia, because it is widely appreciated that once the placenta is removed (i.e. the pregnancy is discontinued), preeclampsia resolves. It is precisely this dictum that is responsibility for the preterm birth burden of this condition.

#### 53.3.1 Normal Placentation

As mentioned, normal placentation is characterized by two distinct processes of trophoblast invasion: invasion of the decidua and invasion of the spiral arteries.

In normal placentation anchoring villi, consisting of villous cytotrophoblast, must first invade and thereby attach to the decidua. The cells of the anchoring villous proliferate and some develop into progenitors of extravillous cytotrophoblast cells. The latter detach from the anchoring villi in the first weeks of pregnancy and migrate through the decidua as interstitial cytotrophoblast (Figure 53-1). A subset of these cells invades the spiral arteries. The endovascular invasion of the spiral arteries by interstitial cytotrophoblast cells is thought to occur at two distinct times in pregnancy; the first occurs during the first trimester probably around 12 weeks gestation, and the second wave of invasion peaks in the second trimester (16–20 weeks) (18). The invasion of spiral arteries by cytotrophoblast cells results in plugging followed by recanalization (pseudovascuogenesis) of the spiral arteries and then replacement of endothelium and vascular smooth muscle cells (Figure 53-2). During normal pregnancy, this process takes place along the length

**FIGURE 53-1** The relationship of anchoring villi, decidua, and spiral artery at implantation. A population of extravillous cytotrophoblast migrates toward the spiral artery.

**FIGURE 53-2** Migration of extravillous cytotrophoblasts results in endovascular invasion of the spiral artery. Trophoblasts replace endothelial cells and vascular smooth muscle cells. The result is a low resistance and dilated spiral artery.

### Implantation of anchoring villi

**FIGURE 53-3** A shift in the balance of Th-1 proinflammatory to Th-2 anti-inflammatory cytokines is implicated in trophoblast invasion of the decidua.

of the spiral artery endothelium. The process of endovascular invasion is believed to transform spiral arteries into dilated low-resistance conduits of blood flow (19,20,120).

### 53.3.2 Abnormal Invasion of Decidua

A great deal of attention has been paid to the process of early trophoblast invasion into the decidua. Anchoring villi must invade the decidua before extravillous cytotrophoblast can migrate through the decidua to invade the spiral arteries. Furthermore, premature trophoblast cell death could result in the release of toxins and cellular debris into the maternal circulation with downstream systemic effects that characterize the clinical features of this condition (e.g. hypertension, renal dysfunction).

Investigations of the Fas/FasL pathway have provided possible insights surrounding trophoblast invasion of the decidua by anchoring villi structures. It seems clear that this represents a dynamic process requiring a shift in cytokine production from a Th-1-dominated (proinflammatory) to a Th-2 dominated (anti-inflammatory) milieu (Figure 53-3). The critical cytokines in the former are IFN- $\gamma$  and TNF- $\alpha$  and those in the latter group are IL-6 and IL-10. Regulation of the Fas/FasL pathway by cytokines appears to be a well-established process in normal invasion of the decidua (Figure 53-4) (12). The exact origin of the cytokines responsible for the Th-1 to Th-2 shift—whether from macrophages or natural killer cells—is less certain. When first-trimester trophoblast cells derived from a cell line (H8) are exposed *in vitro* to serum from patients with preeclampsia, cell viability was reduced and the Fas/FasL pathway was implicated (116).

Originally, the Fas/FasL pathway was described as a regulator of the life span of peripheral blood activated mature T-cells (113,140,141). Fas (CD95) is a marker of activated T-lymphocytes and is also found as a soluble molecule in serum. Fas is a membrane protein (TNF-R superfamily) and in the immune system, is a marker of activated T-cells where it is the initiator of apoptosis.

**FIGURE 53-4** IL-10 upregulates the expression of Fas, however, apoptosis is not increased because IL-10 also upregulates FLIP. FLIP binds (red bars) to pro-caspase-8, which prevents cleavage to the active enzyme caspase-8. Trophoblast cells remain viable and capable of implantation.

Soluble Fas is present in serum too and in this form is capable of binding to FasL and thus prevent apoptosis. Many investigators have implicated cell-mediated immunity in the pathogenesis of preeclampsia (100,124,130). Peripheral blood CD8<sup>+</sup> T cells obtained from patients with preeclampsia demonstrated greater expression of Fas compared to controls, suggesting enhanced cell-mediated immunity. In addition, soluble Fas in serum was greater suggesting an accumulation of these cells and slower turnover due to the decreased availability of FasL (82).

### 53.3.3 Abnormal Invasion of Spiral Arteries

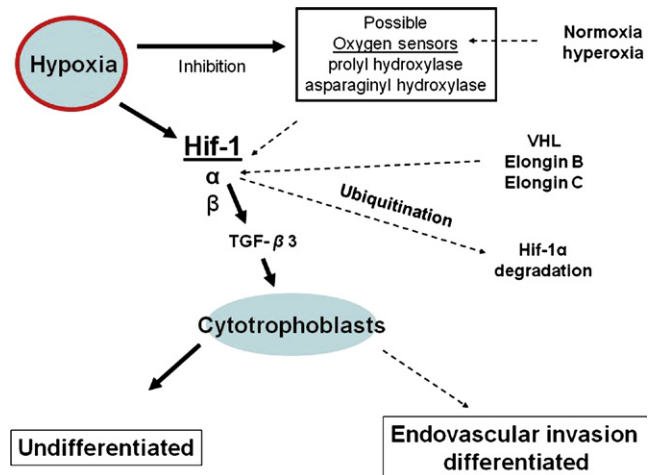

**53.3.3.1 Histologic Features.** Supporting the clinical observations that implicate the placenta in the pathogenesis of preeclampsia are abnormal histologic features of trophoblast cells (Table 53-4) and the spiral arteries. Cytotrophoblast cells from placentas of patients with preeclampsia have distinctly different cell adhesion markers and invasive properties compared to cells from control placentas (Table 53-3). There is less transformation of spiral arteries by cytotrophoblast and they appear to be occluded by fibrin, IgM, complement (C<sub>3</sub>), apolipoprotein-a, platelets, lipid-laden macrophages, and leukocytes (80,86,106,128). In aggregate, these make up the histologic lesion called “acute atherosclerosis,” which is considered to be the pathognomonic lesion of the placenta in preeclampsia (157). There is, however, some overlap between “acute atherosclerosis” of the placenta described in preeclampsia and the lesion seen in cases of idiopathic fetal growth slowing (IUGR), chronic hypertension, and miscarriage also conditions with a placental origin (18,53,106). In the latter conditions, the defining features of preeclampsia, hypertension and proteinuria are absent. The observation of a similar lesion has led to speculation that acute atherosclerosis occurs secondary to more “upstream” etiologic events (120).

**TABLE 53-4 Histologic Change in Trophoblast from Patients with Preeclampsia vs Normal Pregnancies (6,8,11,17,70)**

Syncytiotrophoblast	Smaller Mass Higher Glycogen Content
Interstitial Cytotrophoblast	Shallow Invasion Greater Number
Endovascular Trophoblast	Fewer Numbers Fewer Vessels Transformed Patchy and Discontinuous

**53.3.3.2 Oxygen and the Microenvironment.** The triggers for abnormal cytotrophoblast differentiation and migration toward the spiral arteries are not completely understood. Recent work implicates altered oxygen concentrations at the maternal–fetal interface (Figure 53-5). When villous explants are cultured under hypoxic conditions, they are induced to proliferate (47,79); however, assays of differentiation that rely on cell surface protein expression suggests a failure to differentiate (51,52). The proliferative response to hypoxic conditions may be mediated by the transcription factor Hif-1. Hif-1 has  $\alpha$  and  $\beta$  subunits. It is the  $\alpha$  subunit that is upregulated during hypoxic conditions, whereas, under either normoxic or hyperoxic conditions, the degradation of this subunit occurs (102). Within placental tissue, Hif-1 was shown to be upregulated during conditions of hypoxia within the placental microenvironment in vivo and in vitro experiments (123,150). Hif-1 also appears to regulate transcription of TGF- $\beta$  3 (131). Strong evidence suggests TGF- $\beta$  3 inhibits differentiation and endovascular invasion by cytotrophoblasts (24,25). Thus, Hif-1 may be a key regulator of gene expression important in trophoblast differentiation and migration.

**53.3.3.3 Immune Regulation of Trophoblast Migration.** It is remarkable that placental implantation proceeds uninterrupted despite having the potential, as a semi-allogenic graft, to initiate rejection by the maternal immune system (107). Tissue is rejected by the maternal immune system through the interaction of several cell types and antigens. Unchallenged observations, related to the interaction of fetal antigens and maternal capacity to reject fetal tissues, include the lack of classical HLA Ia gene expression by trophoblast cells (45,55,69), the expression of nonclassical HLA-G by extravillous trophoblast, and trophoblast cells that make up distal anchoring villi (42,84). Key cell types at the maternal–fetal interface include maternal immunoreactive cells (natural killer (NK) cells, and CD8<sup>+</sup> and CD4<sup>+</sup> T-Lymphocytes) and fetoplacental cytotrophoblast (villous and extravillous). NK cells are the primary macrophage subtype in the decidua. NK cells have the ability to destroy the cells that lack classical HLA (class Ia) antigens (A, B, and C), such as tumor cells and cytotrophoblast. They can also initiate a viral immune

**FIGURE 53-5** Hypoxia within the microenvironment of implantation may be responsible for abnormal placentation observed in preeclampsia. The  $\alpha$ -subunit of the transcription factor Hif-1 is under control of oxygen sensors and ubiquitinated under normoxic or hyperoxic condition. Solid line, hypoxia; dashed line, normoxia.

**FIGURE 53-6** Migration of extravillous-interstitial cytotrophoblast is permissive through interactions of HLA-G and KIR receptors on NK cells. Lysis of foreign cells is prevented subsequent to these interactions.

response and they can secrete cytokines in response to various stimuli. In addition to receptors that promote lysis or production of cytokines, NK cells have killing inhibitory receptors (KIR). Protein interactions include those between membrane-bound and soluble HLA-G, and the receptors on NK cells, CD8<sup>+</sup>, and CD4<sup>+</sup> cells. At least two noncompeting theories of immune tolerance at the maternal–fetal interface have been put forth. One holds that cytotrophoblasts that express HLA-G can migrate safely through the decidua to invade the maternal spiral artery without being lysed by NK cells (Figure 53-6). The protective effect of HLA-G is likely mediated through KIR on NK cells. There are at least three NK KIR (LIR-1/ILT2, p49, and BY55) that interact with HLA-G (5,26,36). However, trophoblast cells are resistant to NK cell lysis (15,78). Another mechanism (Figure 53-6) holds that through the interaction of HLA-G with

alternative subsets of KIR on NK cells, cytokine production (IL-3 and IL-1 $\beta$ ) is decreased while tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and interferon- $\gamma$  are increased (73,99). Evidence suggests that cytokines are important in the process of vascular invasion by extravillous trophoblast cells (13). Thus, HLA-G offers “immune privilege” to trophoblast cells and its presence may be important in guarding against the development of preeclampsia (90).

### 53.3.4 Serum Toxins and Endothelium

The multiorgan nature of preeclampsia is thought to be due to widespread endothelial dysfunction and decreased organ perfusion (127). The factors that lead to this are not clear. The longest surviving theory held that the placenta produced toxins that were released into the maternal blood stream. This gave rise to the terms “toxemia of pregnancy,” which were the earliest used to describe the clinical entity—preeclampsia (40). Observations that serum from patients with preeclampsia has mitogenic and cytotoxic effects on endothelial cells and fibroblasts, respectively, lend support to the theory of circulating toxins (129,144). Mediators of apoptosis (e.g. soluble Fas) and angiogenesis have been proposed and are found to circulate at varied levels among patients with preeclampsia compared with controls. These could function as the reputed circulating factors proposed by others.

Apoptosis is one explanation for the derivation of serum toxins originating from placental tissue. The relationship between the Fas/FasL pathway has been studied with respect to trophoblast invasion of the spiral arteries too. It seems the expression of FasL by migrating trophoblast cells induces apoptosis of activated lymphocytes (75). Thus, the Fas/FasL pathway may be important in both processes of trophoblast invasion—decidua for attachment and spiral artery invasion for appropriate perfusion. This apoptosis pathway may also play a role in recanalization of spiral arteries (pseudovasculogenesis) plugged by trophoblast after vascular invasion, and the subsequent death of endothelial cells that line the spiral arteries (14). When pseudovasculogenesis fails to occur, there is a poor placental perfusion and a milieu of low oxygen tension potentially important antecedents of preeclampsia.

Neutrophil activation results in the release of elastase, reactive oxygen species, and leukotrienes that can damage endothelial cells (57). These may play a role in causing widespread endothelial dysfunction. Patients with preeclampsia have higher serum concentrations of cytokines and cell adhesion molecules (93) capable of attracting neutrophils to the endothelium and inciting neutrophil activation, prostaglandin production and the release of superoxide anions and hydrogen peroxide. These free radicals can cause damage when the defense system (e.g. vitamin E, glutathione peroxidase, superoxide dismutase, and catalase) is not maintained or is overwhelmed. Observations of increased oxygen-free

radicals and lipid peroxides along with lowered serum concentrations of vitamin E in cases of more severe disease adds credibility to this theory of hematogenous toxins (71,147,149). Animal models support observations in humans (76,139). Hyperlipidemia normally seen in pregnancy is exacerbated in pregnancies complicated by preeclampsia (121). It is conceivable that abnormal lipid metabolism could contribute to the observations of endothelial cell dysfunction (7). Observations in human pregnancy support these concepts (101,117,151).

Reduced organ perfusion as a cause of organ dysfunction originates from several converging mechanisms. Most simplistically, the increased systemic vascular resistance leads to greater capillary oncotic pressure and proteinuria leads to decreased osmotic pressure (44). The result is a decreased intravascular volume and increased resistance to blood flow, both of which result in the potential for compromised end-organ function. Additionally, peptides such as natriuretic peptides (e.g. atrial natriuretic peptide) function to compensate for hypertension by increasing sodium and water excretion (62,108). Preeclampsia is characterized by decreased intravascular volume (48,63).

If adequate blood supply for the delivery of critical oxygen concentrations, nutrients that maintain homeostasis, and a channel for disposal of metabolic fuel is a determinant of placental development and vascular tone and organ function, then endothelial-dependent relaxation is likely a key process. Arteries from specific tissues of patients with preeclampsia demonstrate alterations in endothelial-dependent relaxation (104) and enhanced pressure response to angiotensin II (1). These observations appear to be secondary to endothelial dysfunction rather than smooth muscle dysfunction. Local regulation of vasoactive substances in tissue beds—especially the uterus—may play an important role in this relaxation (21,54). Altered renal proximal tubular function, activation of the coagulation cascade, and increased sensitivity to vasopressors antedate the overt rise in blood pressure seen in preeclamptic patients. The cause of increased sensitivity to circulating pressor agents such as angiotensin II (50) still requires elucidation. An imbalance of endothelial-derived prostaglandins in favor of the endogenous vasoconstrictor thromboxane as compared to the vasodilator prostacyclin could explain this unusual sensitivity to angiotensin II (22,155). Alternatively, there could be altered regulation of angiotensin II receptor concentrations (16) or nitric oxide production (114).

### 53.3.5 Angiogenic Factors

Angiogenic factors are thought to play an important role in the process of pseudovasculogenesis. The logic is as follows. The process of pseudovasculogenesis is characterized by transformation of trophoblast cells that have plugged the spiral arteries. These cells express a unique set of cell-surface markers (Table 53-4) and assume the role

played by endothelial cells. One well-described angiogenic factor vascular endothelial growth factor (VEGF) is capable of transforming stem cells to endothelial cells (118). When pseudovasculogenesis within the placenta fails, the histologic finding “acute atherosclerosis” is seen.

Recently, attention has been directed to circulating angiogenic proteins, VEGF and placental growth factor (PlGF). Evidence suggests that circulating levels of these proteins may be reduced in patients with preeclampsia. This reduction likely results from the upregulation of the soluble fms-like tyrosine kinase-1, sFlt1, which is similar to VEGF receptor (77,91,103,134). It works to “soak up” circulating VEGF and PlGF; by doing so, the function of these angiogenic factors is lost and pseudovasculogenesis is compromised. In addition to inducing angiogenesis, VEGF is known to stimulate the release of endogenous vasodilatory compounds (e.g. nitric oxide) (64,103,109). Capable of binding VEGF and PlGF, sFlt1 may be an important mediator of the clinical manifestations seen in preeclampsia (103). Furthermore, these molecules may hold promise as biomarkers for disease since changes in serum concentration are seen before the clinical phenotype (91,92).

In summary, that the exact pathogenesis of preeclampsia has remained elusive should not be surprising. This disorder is defined by quantitative traits and as such, the genetic basis is likely to involve multiple genes in multiple pathways. In addition, there are almost certain to be environmental factors that impact gene expression. A common theme in the pathogenesis of this condition is abnormal trophoblast invasion that predisposes the placenta to poor perfusion and apoptosis. The increase in vasomotor tone, a feature of this condition, establishes a cycle of events with poor perfusion a central theme. The cycle is not broken without removal of the offending organ—the placenta (Figure 53-7). Whether a hypoxic milieu, perturbations in the immune system at the maternal–fetal interface, or aberrations in the process of pseudovasculogenesis are the inciting factors on a case-by-case basis seems relevant to the future approaches aimed at prevention and/or treatment of this condition.

## 53.4 GENETIC BASIS OF PREECLAMPSIA

Three lines of evidence support the heritability of preeclampsia. The least robust of those currently available are simple descriptive studies. These were followed by epidemiologic studies that led to views of a Mendelian inheritance pattern. Finally, advancing technologies in genetics enabled the search for genetic associations.

### 53.4.1 Family Studies

The earliest reports of multiple affected family members date to the late 1800s (Table 53-5). These were followed by the first prospective study to document

**TABLE 53-5 Cytotrophoblast Surface Molecules during Control and Preeclamptic<sup>a</sup> Pregnancy (158)**

PECAM-1	+	+	+	+

<sup>a</sup>Results for preeclamptic pregnancies are in shaded rows for each protein.

heritability (34). Among 296 eclamptic women observed between 1931 and 1960, data from 98 of 110 daughters born showed 32% developed preeclampsia in their first pregnancy and 39% developed preeclampsia in any pregnancy. Furthermore, there were 147 sisters of the 296 eclamptic women; 37% developed preeclampsia and 4% became eclamptic. Although a control group was not included in this descriptive study, the data presented support a higher than expected frequency of preeclampsia in some families. This and similar studies (3,9,32,33,37,38,68,94,142) were used to promote the concept that preeclampsia was a Mendelian disorder with either a recessive or a dominant mode of transmission. However, there were flaws in the rationale for supporting a simple Mendelian approach to inheritance. Today, we recognize that preeclampsia is a complex disorder characterized by quantitative traits (hypertension and proteinuria). Thus, multiple genes and possibly environmental factors are implicated in the disease phenotype.

### 53.4.2 Association Studies

With the background from epidemiologic studies that support a single-gene theory for preeclampsia and the ready availability of polymerase chain reaction as a laboratory technique to test for genetic alterations, the natural progression of a search for single genes that might explain this condition was embarked upon. A plethora of genetic association studies followed, and these studies continue to be published today. Some of those that demonstrated positive association (Table 53-6) were often refuted by other investigators within months. In nearly every case, the genes chosen had a biologic basis; however, one could critique patient selection, criteria used to define disease, control groups, and sample sizes

used to draw conclusions. Thus far, genetic association studies have not been transformative in guiding clinical management, disease prediction or prognosis.

### 53.4.3 Genome-Wide Scans

Technologic advances recently led to the application of genome-wide scanning to identifying genomic areas of interest for quantitative traits (Table 53-7). These studies have varied in their general approach and the criteria used to establish linkage. Of note, the literature reflects a general trend toward higher LOD scores over time. Overall, at least six chromosomal regions have been suggested to contribute genes important in preeclampsia, while genes located on chromosomes 2 and 4 have been implicated in more than one study (Table 53-8).

### 53.4.4 Parent of Origin

The suggestion that preeclampsia was rooted in a Mendelian inheritance pattern raised the question of whether any gene effects were due solely to parental genes present in the fetus, the maternal environment owing to mother's genes, or a function of maternal and paternal genes combined. Clinical observations that mothers are less likely to develop preeclampsia in subsequent pregnancies with the same father, and that they establish an increased recurrence risk in subsequent pregnancies with a different father support the importance of a paternal contribution. Animal models lend credibility to theories that favor a combination of maternal and paternal gene effects (74,143). Using a Utah database of children born after pregnancies complicated by preeclampsia, a paternal gene effect was demonstrated (43). When the male children from these pregnancies conceived their own children, pregnancies were complicated by preeclampsia nearly two times greater than among control patients (2.7% vs 1.3%, respectively). Thus, it is likely that maternal and paternal genes contribute to the maternal phenotype we define as preeclampsia.

Making sense of these lines of evidence requires an integrated approach, one that recognizes the limitations of the single-gene theory yet accepts that specific genes are important. Preeclampsia fits a quantitative trait model of disease. Therefore, one is left trying to explain its genetics under one of two models: (i) multiple genes with small but equal effects, and (ii) a major gene effect with multiple modifying genes (96). However, neither model is mutually exclusive. The first model would argue a normal distribution of the phenotype (e.g. hypertension), while the second would argue a skewed distribution. The possibility of time-specific expression of a major gene (skewing of the phenotype) over the course of pregnancy cannot be excluded after considering available evidence (83).

## 53.5 ANIMAL MODELS

There has been a paucity of data derived from nonhuman primates that can be used to explain the pathogenesis or redefine therapies for preeclampsia. Despite early reports that showed that nonhuman primates with placental ischemia had clinical features of preeclampsia (27), other species have received greater attention. Exploiting a candidate pathway recognized for its importance in physiologic studies (49) and for which genetic association was suggested, investigators perturbed the renin/angiotensin system in mice. Pregnant female mice that overexpressed human angiotensinogen and were exposed to excess human renin from placental tissue demonstrated features remarkably similar to preeclampsia, including late-pregnancy hypertension and proteinuria (143). Nitric oxide, a potent endogenous vasorelaxing autoid, was investigated. Rats exposed to an inhibitor of nitric oxide synthase showed progressive hypertension with reduced growth of pups (153). Contrary to these

observations, a mouse model with a targeted disruption of endothelial nitric oxide synthase demonstrated higher blood pressure throughout pregnancy, but no evidence of proteinuria (59,65). Two additional rodent models of preeclampsia have been described. A mouse line (BPH/5) with spontaneous hypertension shows late-pregnancy hypertension with normalization of blood pressure postpartum in addition to proteinuria and renal lesions seen in human disease. The genetic perturbations in this line are unknown (39). Recently, the paternally imprinted cyclin-dependent kinase inhibitor gene, *p57Kip2*, has been implicated and the phenotype is strikingly similar to preeclampsia. A decrease or loss of expression of this gene in mice results in placental development that is similar to that observed in some cases of human disease (74). The precise utility of the animal models described, which demonstrate features of preeclampsia, is unclear. Except for the latter model (i.e. *p57Kip2*) and perhaps the as yet unknown perturbation in the BPH/5 line, models have focused primarily on genes or pathways that likely play a role in the human condition. Although the approach to animal modeling was to substantiate evidence derived from human studies, provide new direction for pathogenesis, and to enable a therapeutic alternative to human disease, each model appears to have fallen short of these goals. However, examinations of all previously described models are incomplete and hold the promise of offering new insights into the genetic basis of preeclampsia.

# Common Genetic Determinants of Coagulation and Fibrinolysis

*Angela M Carter, Kristina F Standeven, and Peter J Grant*

Division of Cardiovascular & Diabetes Research, The LIGHT Labs, University of Leeds, Leeds, UK

## 54.1 INTRODUCTION

Thrombotic disorders are a major cause of morbidity and mortality and can be classified into venous thrombosis, characterized by the deposition of fibrin-rich thrombi, and arterial thrombus, characterized by platelet-rich thrombi superimposed upon atheromatous plaque. Elucidating the mechanisms involved in the development and progression of these disorders has been a major health care initiative for many years. It has become clear that for both venous and arterial thrombotic disorders, abnormalities of hemostasis play a key role.

The hemostatic system maintains a delicate balance between the processes of coagulation and anticoagulation, platelet activation and platelet inhibition, and activation/inhibition of fibrinolysis to achieve hemostasis while conserving vascular patency. Activation of the coagulation cascade and platelets occurs in rapid response to endothelial cell injury, leading to thrombin generation, platelet deposition and fibrin formation (Figure 54-1). Activation of the anticoagulant pathway by interaction of thrombin with membrane-bound thrombomodulin and activation of protein C inhibit further thrombin generation and serve to localize coagulation at the site of vascular injury and prevent widespread systemic coagulation. Finally, the fibrinolytic system helps to maintain vascular patency by lysis of the fibrin matrix.

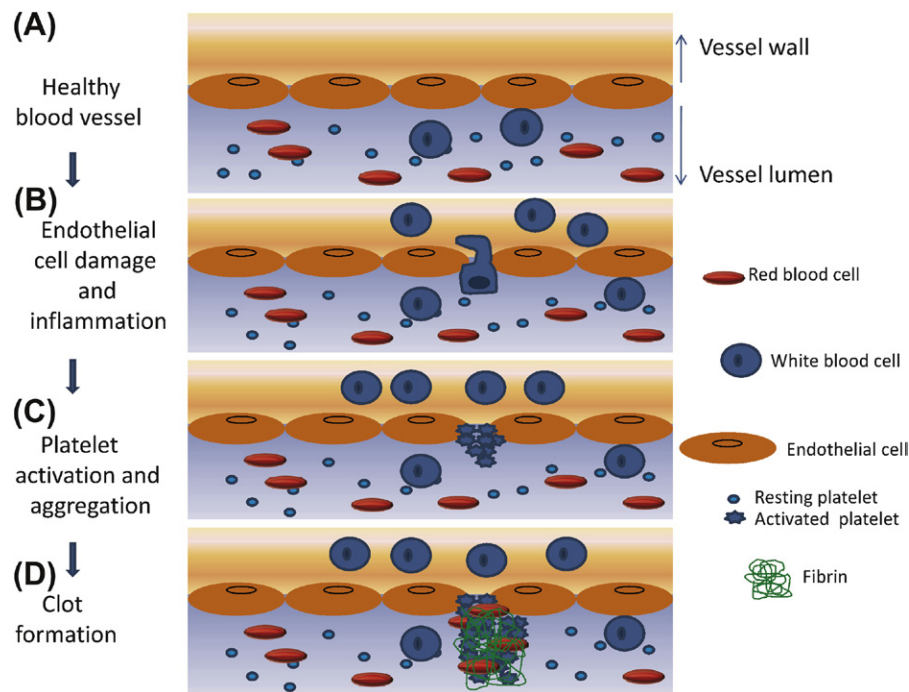

Perturbation of these processes may give rise to bleeding disorders (these tend to be rare familial defects and are not within the scope of this chapter), or to thrombosis. Perturbation of hemostasis may arise through a variety of environmental and genetic influences and ultimately the duration of exposure and the accumulation of risk factors will determine risk of thrombosis.

The venous system is a low-pressure, low-flow environment where a tendency to hypercoagulability has clear links to pathogenesis of disease, particularly where blood flow is compromised, for instance, by periods of immobility. The contribution of genetic factors to

the pathogenesis of venous thrombosis is indicated by a strong family history in many individuals presenting with premature thrombosis. Commonly, deficiencies in the anticoagulant proteins, protein C, protein S and anti-thrombin are identified in these subjects, which highlight the importance of abnormalities of hemostasis, and anticoagulant pathways in particular, in the pathogenesis of venous thrombosis. The contribution of genetic factors to the pathogenesis of venous thrombosis is most apparent in young subjects in whom spontaneous thrombosis may occur without obvious environmental stimuli such as surgery, pregnancy or malignancy.

The development of arterial thrombosis involves complex interactions between environmental and genetic factors. In comparison to the venous circulation, the arterial system is a high-flow, high-pressure system in which the development of atherosclerotic plaques in the vessel wall is followed by plaque instability and rupture, to precipitate the acute thrombotic event. A number of large prospective and case-control studies have addressed whether changes in plasma levels of hemostatic components are related to the pathogenesis of cardiovascular disorders. These studies, which have been reviewed extensively (1–4), have demonstrated associations between several coagulation and fibrinolytic factors (fibrinogen, factor VII (FVII), tissue-type plasminogen activator (tPA) and plasminogen activator inhibitor-1 (PAI-1)) and atherothrombotic events. It is apparent that whatever the predisposing factors, activation of coagulation is intimately involved in both the progression of atherosclerosis and the manifestation of acute thrombosis. As with venous thrombosis, the contribution of genetic factors has been indicated by the clustering of cardiovascular disease (CVD) within families; however, due to the complex pathogenesis of coronary artery disease (CAD), elucidating the genetic factors contributing to acute thrombotic events has proved to be more complicated.

Additive genetic factors contribute to variance in hemostasis components, as evidenced by studies in families and

**FIGURE 54-1** Dynamic process of clot formation. Clotting is initiated upon endothelial cell injury. The normal vessel endothelium is characterized by an anti-inflammatory anti-thrombotic phenotype that maintains vascular patency (A). Proinflammatory cells such as monocytes migrate from the vessel lumen into the vessel wall and release cytokines, which further promote inflammatory cell transmigration (B). Exposure of subendothelial collagen and von Willebrand factor lead to platelet adhesion activation and aggregation forming a platelet plug at the site of injury (C). Exposure of tissue factor at the site of injury initiates activation of the coagulation cascade (Figure 54-2), which results in thrombin generation and the formation of a fibrin mesh that traps circulatory blood cells such as platelets and erythrocytes to enable consolidation of the thrombus (D).

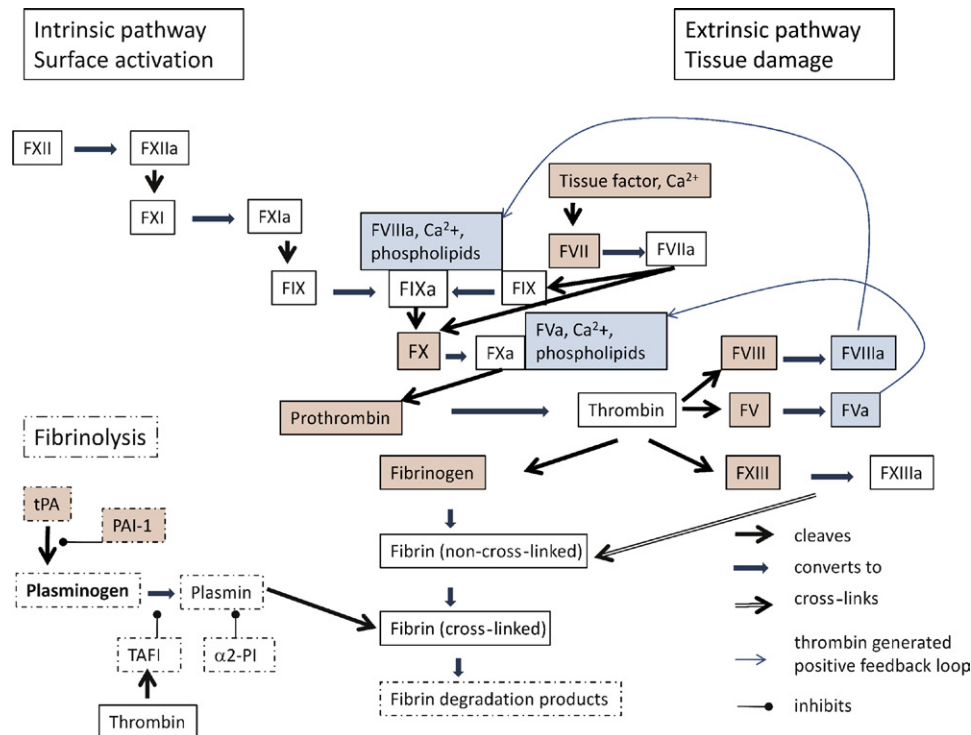

twins, which have identified a significant heritable component for many factors. Potentially, all the genes coding for proteins involved in coagulation, anticoagulation, fibrinolysis and platelet function (Figures 54-1–54-3) are candidate genes for thrombosis. In the Leeds Family study, the heritability estimates for FVII, fibrinogen, factor XIII (FXIII) complex, PAI-1 and tPA were 0.40, 0.37, 0.52, 0.28 and 0.27, respectively (5). Similar heritability estimates have been reported in Spanish families (6), with higher estimates observed in twins (7). A major contribution of additive genetic factors in determining the risk for thrombosis was indicated by the Genetic Analysis of Idiopathic Thrombophilia (GAIT) study, which showed that genetic factors accounted for ~60% of variation in risk (8). Importantly, significant genetic correlations between various hemostatic factors and thrombosis were identified in the GAIT study (8), supporting the concept that genetic variants influencing individual hemostatic factors also influence susceptibility to thrombosis.

Genetic variants contribute to thrombosis in a variety of ways. Nonsynonymous polymorphisms in the genes encoding individual hemostatic components can influence the structure and/or the function of the encoded protein to influence protein/protein interactions or protein concentration through influences on protein secretion or degradation. Polymorphisms in the key regulatory regions of the genes encoding individual hemostatic components can influence mRNA expression or stability to

affect the concentration of the encoded protein. Finally, genetic variants in key regulatory proteins may modulate the posttranslational modification and/or synthesis and secretion of hemostatic components.

Historically, a hypothesis-driven candidate gene approach has been favored in which the genes encoding individual hemostatic components were screened for novel polymorphisms, which were tested for association with intermediate and disease phenotypes, and functional studies carried out to elucidate mechanisms of action. Recent technological advances, including development of systems for high-throughput genotyping, improved bioinformatics methods for data mining and improved statistical methods for data analysis, have enabled identification of genetic variants in putative regulatory regions. In particular, genome-wide analysis of genetic variants associated with intermediate hemostatic phenotypes and thrombotic disorders through linkage analysis in twin- and family-based studies and genome-wide association studies (GWAS) has identified novel factors associated with hemostasis and thrombosis. While genome-wide analyses for disease end points may be criticized for being entirely hypothesis free and frequently difficult to characterize, genome-wide analysis of intermediate phenotypes has the advantage of a more hypothesis-driven approach, with more accurate measurement providing greater opportunities for identifying key regulatory proteins and understanding potential functional effects.

**FIGURE 54-2** The coagulation cascade. Exposure of tissue factor and contact activation lead to the initiation of the clotting cascade, which culminates in the conversion of prothrombin to thrombin. A positive feedback loop results in further activation of cofactors V and VIII, leading to a burst in thrombin activity sufficient to ensure effective fibrinogen conversion. Fibrinogen is cleaved by thrombin to give rise to polymerized fibrin, which in turn becomes cross-linked by FXIII, leading to the formation of a stable fibrin clot. Fibrin formation is counteracted by the activation of the fibrinolytic cascade, in which plasminogen is converted by tissue plasminogen activator (tPA) to plasmin, which digests the fibrin clot, giving rise to fibrin degradation products. The process of fibrinolysis is halted by the incorporation of plasmin inhibitor ( $\alpha$ 2-antiplasmin) and TAFI into the clot (the latter being activated by thrombin). Areas shaded in pink are components of the coagulation/fibrinolysis system, which are discussed in more detail in this chapter. Areas shaded in blue denote cofactor activity.

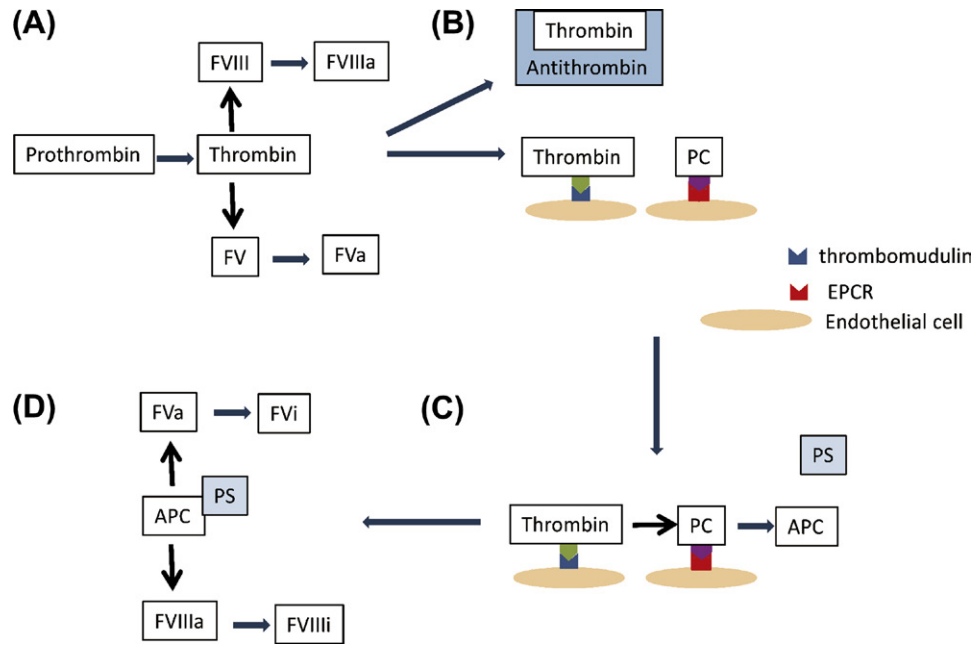

In the following sections of this chapter we describe the common genetic variants influencing coagulation, anticoagulation, fibrinolysis and platelet function that have been associated with venous and/or arterial thrombosis. Particular emphasis is placed on discussing functional polymorphisms where there is evidence of an association of the genetic variants with alterations in the levels or function of the particular protein and where there is evidence of an association of the genetic variants with thrombosis. We also provide relevant information from recent GWAS of hemostatic intermediate phenotypes and thrombotic disease. We conclude this chapter by considering the impact of genetic risk factors on the clinical management of thrombosis.

## 54.2 GENETIC VARIANTS INFLUENCING COMPONENTS OF THE COAGULATION CASCADE

### 54.2.1 Factor VIII and Von Willebrand Factor

Factor VIII (FVIII) circulates in the blood bound to von Willebrand factor (vWF), which protects FVIII from proteolytic cleavage. As vWF concentration is an important

determinant of FVIII concentration, we have considered these proteins together, although genetic variants influencing vWF concentration may also affect platelet function. Elevated plasma FVIII and vWF have been associated with increased risk for vascular disease (9–11). Evidence of a genetic contribution to variance in plasma FVIII and vWF levels originated from observation of associations between FVIII, vWF and ABO blood group, with the lowest levels observed in those of blood group O, and clustering of FVIII and vWF levels in families (12). Viel et al. (13) carried out resequencing of the exons and splice junctions of the gene encoding FVIII (*F8*) in individuals without hemophilia to identify genetic variants associated with variance in FVIII concentration. They identified 47 polymorphisms across the gene, which showed considerable racial differences in frequency. Two variants, D1241E and 56010G>A (in intron 7), were associated with plasma FVIII concentration, although these single-nucleotide polymorphisms (SNPs) were in strong linkage disequilibrium. Further analysis of D1241E indicated that this SNP accounted for ~10% of variance in FVIII independent of other covariates including ABO genotypes, indicating that it may be functional or in linkage disequilibrium with a functional polymorphism in *F8* (13).

**FIGURE 54-3** Natural anticoagulants. Thrombin generated by the coagulation cascade (A, see Figure 54-2) also exhibits an anticoagulant effect by binding to thrombomodulin situated on endothelial cells (B). Free thrombin is inhibited by binding to antithrombin (B). Thrombin then undergoes a functional switch and cleaves protein C bound to endothelial protein C receptors (C). This leads to activation of protein C (APC), which together with cofactor protein S inhibits the coagulation process by cleaving FVa and FVIIIa to their inactive cleavage products FVi and FVIIIi, thus inhibiting the positive feedback loop of thrombin generation (D).

Common polymorphisms in the vWF gene (*VWF*) have been identified, including four within the 5' gene regulatory region: -1793 C/G, -1234 C/T, -1185 A/G, and -1051 G/A (14,15). Differences in nuclear protein binding have been reported for -1234 C/T and -1051 G/A, and -1234 C/T, -1185 A/G and -1051 G/A polymorphisms are in strong linkage disequilibrium forming two major haplotypes (haplotype 1: -1234C/-1185A/-1051G; haplotype 2: -1234T/-1185G/-1051A) (15). These haplotypes associate with plasma vWF levels in subjects of blood group O, with highest levels in subjects homozygous for haplotype 1 and lowest in those homozygous for haplotype 2 (15). In the population-based Rotterdam Study, the -1793 C/G polymorphism was associated with risk for CVD, but only in individuals with advanced atherosclerosis at baseline (16).

A recent GWAS analysis of FVIII and vWF in >20,000 individuals identified 191 SNPs associated with FVIII concentration and 400 SNPs associated with vWF concentration with genome-wide significance ( $p < 0.5 \times 10^{-8}$ ) (17). SNPs associated with FVIII were localized to five chromosomal regions (6q24, 8p21, 9q34, 12p13, and 12q23) and SNPs associated with vWF were localized to eight chromosomal regions, five of which coincided with those for FVIII with an additional three unique loci (12q24.3, 14q32, and 19p13.2). The complete concordance of genetic loci for FVIII with those for vWF supports vWF as a major determinant of plasma FVIII concentration. For the 9q34 locus, SNPs spanned 11 genes including *ABO* and after accounting for SNPs tagging *ABO* blood groups, no other SNPs were

significantly associated with FVIII or vWF in this region, suggesting that *ABO* is the functional gene, supporting previous studies. SNPs in the 12p13 locus were localized to *VWF*, with rs1063857, a synonymous SNP at amino acid 795, giving the highest p value. Interestingly, SNPs in the *F8* gene were not identified as a significant determinant of FVIII or vWF in this study. The most informative SNPs at the 6q24, 8p21, 12q23, 12q24.3, 14q32, and 19p13.2 loci were in the vicinity of the genes encoding syntaxin-binding protein 5 (*STXBP5*, rs9390459); scavenger receptor class A, member 5 (*SCARA5*, rs2726953); stabilin 2 (*STAB2*, rs4981022); syntaxin 2 (*STX2*, rs7978987); tandem C2 domains, nuclear (*TC2N*, rs10133762); and C-type lectin domain family 4, member M (*CLEC4M*, rs868875), respectively. The SNPs in this study accounted for ~10% of variance in FVIII and ~13% of variance in vWF and support *ABO* as an important determinant of both FVIII and vWF, through influences on vWF (17). The novel candidate genes for FVIII/vWF regulation included genes with putative roles in Weibel–Palade exocytosis and protein uptake/clearance (17). The influence of these genetic variants on venous and cardiovascular thrombosis is currently unknown.

### 54.2.2 Factor VII

FVII is a vitamin K-dependent coagulation factor circulating as an inactive zymogen; FVII is essential for tissue-factor-dependent activation of coagulation. In the Northwick Park Heart Study, elevated levels

of FVII coagulant activity were associated with fatal (but not nonfatal) coronary events (18). However, this association has not been substantially confirmed by other large studies (19,20). Six common polymorphisms have been identified within the FVII gene (-122 T/C, -401 G/T, -402 G/A, a 10bp insertion at -323, Arg353Gln, and an intron 7 polymorphism), giving rise to three different alleles H5, H6 and H7 (21–23). The 10bp insertion and Arg353Gln are in strong linkage disequilibrium and account for approximately 20% of variance in plasma FVII. Gln353 is less efficiently secreted than Arg353 in vitro and associated with lower plasma FVII levels (24). Alleles -401 G/T and -402 G/A together account for ~30% of variation in plasma FVII levels, with -401G and -402A alleles associated with increased transcriptional activity in vitro and elevated plasma FVII levels (22). In relation to disease, the association of these polymorphisms with CAD remains controversial, with most studies showing no association; this issue has been discussed in detail elsewhere (25).

Smith et al. (17) carried out GWAS analysis of FVII and identified 305 SNPs associated with FVII at genome-wide significance. SNPs were clustered in five distinct chromosomal regions, 2p23, 4q25, 11q12, 13q34, and 20q11.2. SNPs in 13q34 localized to the FVII structural gene (*F7*) and nearby genes including the gene encoding factor X (FX) (*F10*). After adjusting for Arg353Gln, 22 SNPs localized to *F10* (rs 3211727) and *MCF2L* (*MCF.2* cell-line-derived transforming sequence-like, rs1755693) retained GWAS significance. SNPs in 2p23 were localized to the glucokinase regulatory protein gene (*GCKR*; rs1260326: P446L) and those in 4q25 to the alcohol dehydrogenase genes (rs1126670 and rs896992, respectively). SNPs in 11q12 localized to genes encoding members 2 and 6A of the membrane spanning four domains, subfamily A (*MS4A2* and *MS4A6A*; rs11230180 and rs2847666, respectively). The functional relationship between these proteins and FVII is unclear at present. SNPs in 20q11.2 were in strong linkage disequilibrium with a nonsynonymous SNP in the gene encoding the protein C receptor (*PROCR*; rs867186: S219G). This finding is consistent with evidence indicating that the protein C receptor binds FVIIa leading to endocytosis (26) and that FVII and FVIIa are higher in individuals possessing the G219 allele (27).

### 54.2.3 Factor V

Factor V (FV) plays central roles in both coagulation and anticoagulation processes. Activated FV (FVa) is a cofactor in the conversion of prothrombin to thrombin, whereas zymogen factor V acts as a cofactor with protein S for activated protein C-mediated inhibition of FVIIIa (28). Resistance to activated protein C (APCR) is strongly associated with venous thromboembolism (VTE) (29) and a missense polymorphism of the

factor V gene (Arg506Gln, Factor V Leiden) accounts for the majority of the observed APCR (29). Gln506 is the most commonly occurring genetic risk factor for venous thrombosis identified to date, occurring in ~5% of Caucasians, although there are considerable regional differences in incidence. The Gln506 variant of FVa is less readily inactivated by APC and is less effective as a cofactor for the inactivation of FVIIIa, leading to a hypercoagulable state (reviewed by Lane and Grant (25)). The risk for venous thrombosis associated with Gln506 is estimated to be between 3- and 8-fold in heterozygotes and as high as 50- to 80-fold in homozygotes. A number of other polymorphisms of the FV gene have been identified, one of which (A4070G) gives rise to His1299Arg. A haplotype including nine FV polymorphisms always associates with Arg1299 and is referred to as HR2. This haplotype has been associated with reduced plasma FV levels (30), APCR (even in the presence of Gln506) and risk for VTE in some studies (31,32). A recent meta-analysis supported a statistically significant relationship between both Gln506 and HR2 and venous thrombosis (33).

### 54.2.4 Prothrombin

The conversion of prothrombin to thrombin is the final step in the common coagulation pathway, thrombin acting to convert fibrinogen to fibrin and activate FXIII and platelets. A polymorphism in the 3'-untranslated region of the gene, G20210A, occurs at the last base of the prothrombin mRNA before the poly(A) addition site (34) and is associated with plasma levels of prothrombin, with highest levels in those homozygous for the 20210A allele (34,35). A number of mechanisms have been proposed to explain this relationship, including effects on mRNA processing and stability (36–39). Allele 20210A has been related to VTE, which in the Leiden Thrombophilia Study was accounted for entirely by its association with plasma prothrombin level (34). An additional polymorphism of the prothrombin gene, A19911G in intron M, also relates to plasma prothrombin levels (40) and influences prothrombin mRNA splicing efficiency (41). An interaction between the G20210A and A19911G polymorphisms in relation to venous thrombosis has been reported in a number of studies (40,42,43).

### 54.2.5 Fibrinogen

Fibrinogen (or Factor I) is a soluble glycoprotein (GP) with a central role in blood clotting both as the substrate for fibrin formation and as the ligand for the platelet  $\alpha_{IIb}\beta_{III}$  receptor, which promotes platelet aggregation. Thrombin cleaves fibrinogen to fibrin monomers, which spontaneously polymerize to form half-staggered protofibrils. These aggregate to fibers and result in a three-dimensional fibrin network stabilized by activated FXIII, which serves as a scaffold for the emerging blood clot. Fibrinogen is a

large and complex protein comprising pairs of three non-identical polypeptides linked by a central domain. The subunits are referred to as  $\alpha$ ,  $\beta$  and  $\gamma$  chains (roman capital letters denoting intact chains prior to proteolytic cleavage by thrombin), which are encoded by separate genes (*FGA*, *FGB*, *FGG*) located in the fibrinogen module on the short arm of chromosome 4 (44,45). Individual chains are produced and assembled in hepatocytes. In addition to its function as a coagulation factor, fibrinogen is also an acute phase protein, and raised levels have been consistently associated with CVD (18,46,47). Both environmental and genetic factors influence fibrinogen levels, and in heritability studies, the contribution of genetic factors to plasma levels of fibrinogen have been estimated to be in the region of 50% (5,6,48). There are a number of polymorphisms in all three chains, but in vitro studies suggest that  $\beta$ -chain synthesis is rate limiting in the synthesis of the fibrinogen molecule and research has focused on this area. The substitution of G to A in fibrinogen  $\beta$ -455 is consistently associated with increased fibrinogen levels, in addition to promoter polymorphisms of the fibrinogen  $\beta$  gene (-1420G/A, -993C/T and -148 C/T), which are in complete linkage disequilibrium with  $\beta$ -455 G/A. All three fibrinogen genes have interleukin (IL)-6 responsive sequences, but only SNPs in the  $\beta$ -chain have been shown to modulate fibrinogen synthesis in response to IL-6 (49). This may explain why some environmental factors, such as smoking, result in higher plasma fibrinogen levels only in carriers of these SNPs, and underlines the confounding effect of genetic and environmental factors on plasma fibrinogen. More recent work identified common SNPs and haplotypes of the *FGA* and *FGB* genes as a major determinant for the variability of fibrinogen levels, concluding that genetic background represents a major determinant of fibrinogen, which modulates the response to proinflammatory stimuli (50). Two coding polymorphisms have been identified to date (Arg448Lys in the  $\beta$ -chain, and Thr312Ala in the  $\alpha$  chain). Arg448Lys is in strong linkage disequilibrium with  $\beta$ -chain promoter polymorphisms and is associated with variation in plasma fibrinogen levels, functional properties of the fibrinogen molecule (51) and fibrin phenotype. Clots formed from recombinant as well as plasma-purified Lys448 fibrin have a more compact structure with thinner fibers and smaller pores and increased stiffness, even before cross-linking by FXIII (51). In addition, clots made from fibrinogen-depleted plasma substituted with recombinant Lys448 clots are more difficult to lyse (51). Such phenotypic properties have been associated with increased risk for CVD (52–55). In clinical studies, the Lys448 allele was associated with severity of CAD (56) and with stroke in female patients (57). In Caucasians, the polymorphism is estimated to occur at a frequency of 15–20%.

Thr312Ala occurs in a region of  $\alpha$ -fibrinogen important in a number of FXIII-dependent processes, including  $\alpha$ -fibrin/ $\alpha$ -fibrin and  $\alpha$ -fibrin/ $\alpha$ 2-antiplasmin cross-linking (amino acid residues A $\alpha$ 328 and 303, respectively

(58,59)). The region of  $\alpha$ -fibrinogen encompassing this polymorphism (residues A $\alpha$  242–424) is important in promoting the dissociation of the FXIII A and B subunit dimers thereby enhancing activation of FXIII itself (60,61). We found that fibrin clots formed from plasma-purified Ala312 fibrinogen have increased  $\alpha$ -chain cross-linking, fibrin fiber diameter and clot stiffness compared with clots from Thr312 fibrinogen (62). In clinical studies we reported associations of the Ala312 allele with poststroke mortality in subjects with atrial fibrillation (63) and with pulmonary embolism (64) supporting a role for Ala312 in clot stability. Ala312 is in linkage disequilibrium with a haplotype on *FGG* that is associated with decreased plasma levels of the gamma chain variant  $\gamma'$ . This modified version of the gamma chain arises from alternative processing of  $\gamma$ -fibrinogen mRNA resulting in the inclusion of intron 9 and polyadenylation of the transcript at an alternative polyadenylation site in intron 9 (65). This leads to replacement of the last 4 amino acids by 20 alternative amino acids, which significantly alters the properties of the  $\gamma$  chain (see also review by Uitte de Willige (66)). Between 7 and 15% of plasma fibrinogen molecules contain  $\gamma$ A/ $\gamma'$ , which has been shown to bind FXIII zymogen, and it may represent a mechanism whereby the local concentration of FXIII is increased during clot formation (67). Fibrinogen  $\gamma'$  has a decreased platelet aggregation potential. Interaction of fibrinogen with the platelet  $\alpha_{IIb}\beta_3$  receptor is decreased in recombinant, homodimeric (A $\alpha$ B $\beta$  $\gamma'$ )<sub>2</sub>, indicating that the binding of platelets to the fibrinogen  $\gamma$  chain is mediated by the four C-terminal residues of the  $\gamma$ A chain (68). Clots made from  $\gamma$ A/ $\gamma'$  fibrinogen in the presence of FXIII are more highly cross-linked and lyse more slowly than clots from  $\gamma$ A/ $\gamma$ A fibrinogen (69), and  $\gamma$ A/ $\gamma'$  fibrinogen has also been shown to enhance the activation of FXIII (70). Furthermore, clots formed with  $\gamma$ A/ $\gamma$  fibrinogen have a thinner average fiber diameter and a higher proportion of branch points than clots formed from  $\gamma$ A/ $\gamma$ A fibrinogen (71). A functional role for  $\gamma$ A/ $\gamma$  fibrinogen in thrombosis is supported by findings by Lovely et al. (72) who found that  $\gamma$ A/ $\gamma'$  fibrinogen levels are increased in patients with CAD compared with healthy controls. Similar findings were reported by Mannila et al., (73) who found significantly increased  $\gamma$ A/ $\gamma'$  levels in patients with myocardial infarction (MI) compared to age- and sex-matched controls. In contrast, Uitte de Willige et al. (74) report decreased  $\gamma$ A/ $\gamma'$  levels in patients suffering from deep venous thrombosis (DVT) compared to healthy controls in the Leiden Thrombophilia Study. This could suggest that the relationship between the  $\gamma'$  splice variant and thrombosis is dependent on the type of CVD, and exerts a pro-thrombotic effect in arterial disease, but is associated with protection against thrombotic events in venous disease. The putative mechanisms behind these observations—potentially mediated by differences in fibrin structure, platelet binding and FXIII activation—require further investigation.

Owing to the consistent association of increased plasma fibrinogen with CVD and heritability of ~50%, a number of studies have searched for loci associated with variance in plasma fibrinogen and two recent studies have reported GWAS analysis for plasma fibrinogen (75,76). In the study by Dehghan et al., (75) which involved a meta-analysis of >20,000 individuals from six independent studies, 73 SNPs localized to four chromosomal regions were identified with GWAS significant associations with fibrinogen. The most significant SNP was rs1800789 at 4q31.3 within the FGB gene; this SNP is in linkage disequilibrium with the -148 C/T and -455 G/A polymorphisms, which have been consistently associated with plasma fibrinogen (see earlier). Rs2522056 and rs1539019 were the most significant SNPs at 5q23.3 (3' to the gene encoding interferon regulatory factor 1 [*IRF1*]) and 1q44 (NLR family, pyrin domain containing 3 isoforms [*NLRD3*], respectively, both of which are involved in the regulation of inflammatory processes (75)). Rs511154 at 3q22.3 occurs in intron 1 of the gene encoding propionyl coenzyme A carboxylase  $\beta$ -polypeptide [*PCCB*]. Together these polymorphisms accounted for <2% of the variance in fibrinogen. In an independent study of >17,000 healthy participants in the Women's Genome Health Study, Danick et al. (76) identified 19 SNPs meeting GWAS significance, localized to five distinct chromosomal regions. The strongest associations were with SNPs in 4q32.1 in the vicinity of the fibrinogen structural genes (rs6056 and rs1800788 were the most informative SNPs in this region), supporting the findings of Dehghan et al. The most significant SNP at 1q21.3 was rs8192784 (76), a nonsynonymous Asp358Ala polymorphism in the gene encoding the IL-6 receptor (*IL6R*), which has been shown to influence plasma levels of soluble IL6R and IL-6 (77). The other significant SNPs were rs7422339, a nonsynonymous Asp1405Thr polymorphism at 2q34 (carbamoyl phosphate synthetase 1 [*CPS1*]), rs1016988 and rs10479002 at 5q31.1 (solute carrier family 22, members 4 and 5 [*SLC22A4*, *SLC22A5*]) and rs10512597 at 17q25.1 (in the vicinity of a cluster of immunoglobulin superfamily members including *CD300LF*). Together these SNPs accounted for <2% of the variance in fibrinogen. Interestingly, rs8192284 and rs10512597 were also associated with plasma C-reactive protein (76), highlighting the role of inflammatory factors in the regulation of fibrinogen.

### 54.2.6 Factor XIII

Zymogen FXIII is a transglutaminase that, when activated, plays a crucial role in fibrin clot formation by cross-linking adjacent  $\gamma$  and  $\alpha$  chains of polymerized fibrin, to ensure the structural integrity of the clot (78). To convert FXIII to activated FXIII (FXIIIa), thrombin cleaves a 37 amino activation peptide from the N-terminus of the A-subunit. In addition to clot stabilization, FXIIIa incorporates plasmin inhibitor ( $\alpha$ 2-antiplasmin)

into the growing clot, which significantly increases resistance to lysis by plasmin. FXIII deficiency is associated with severe bleeding but there is little information regarding elevated plasma FXIII and vascular disease. Results from animal studies indicate that FXIII is a major determinant of endogenous and exogenous fibrinolysis and suggest associations with MI and pulmonary embolism (79,80). Common polymorphisms of the FXIII gene have been identified, including four missense polymorphisms, Val34Leu, Pro564Leu, Val650Ile and Glu651Gln (81,82). While none of these polymorphisms are linked to plasma levels of FXIII A subunit antigen or FXIII B subunit antigen, Val34Leu and Pro564Leu are significantly associated with FXIII cross-linking activity, with enhanced activity associated with possession of Leu34 and Pro564. Joint linkage and association analysis indicated that Val34Leu is the predominant genetic determinant of FXIII activity (83). The substitution in codon 34 is three amino acids away from the thrombin cleavage site between Arg37 and Gly38 and results in major changes in functionality of the protein. Activation of Leu34 FXIII by thrombin occurs more rapidly than Val34, with a 2.5 increase in catalytic efficiency (84). Work from our group has shown that these differences in cleavage rates lead to cross-linking at different times during the fibrin polymerization process, which influence fibrin clot properties, with Val34 clots characterized by thin fibers and small pores and Leu34 clots by thicker fibers and a more porous gel. Furthermore, the Leu34 allele is activated at a lower concentration of thrombin than the Val34 allele (85). Val34Leu is the only FXIII polymorphism that has been consistently associated with vascular disease in a number of case-control studies of venous and arterial thrombosis; weak but significant inverse associations of Leu34 with MI and VTE are supported by several meta-analyses (33,86–88).

## 54.3 GENETIC VARIANTS INFLUENCING NATURAL ANTICOAGULANTS

### 54.3.1 Thrombomodulin

Thrombomodulin is an endothelial cell thrombin receptor that converts thrombin into an anticoagulant capable of activating protein C, suggesting a protective role in thrombosis. An inverse association between soluble thrombomodulin and risk of coronary heart disease was reported in the Atherosclerosis Risk in Communities (ARIC) Study (89). Thrombomodulin plays additional functional roles in the downregulation of fibrinolysis and inflammation through activation of thrombin-activatable fibrinolysis inhibitor (TAFI) (see the review by Weiler and Isermann (90) for further information). Polymorphisms of the thrombomodulin gene (*THBD*) have been identified, including several promoter polymorphisms, many of which are of very low frequency, and a more common missense polymorphism Ala455Val (91,92). Information

regarding relationships between polymorphisms and levels of soluble thrombomodulin are inconsistent, although the rare -33 G/A polymorphism confers a weak decrease in promoter activity in a luciferase reporter gene assay (93). Association studies of thrombomodulin gene variants with thrombosis have been contradictory (91,92). However, in a murine model involving targeted endothelial cell deletion of thrombomodulin, deficiency resulted in spontaneous, and ultimately lethal, arterial and venous thrombosis, which could be prevented by treatment with warfarin, suggesting a direct effect on coagulation rather than inflammation (94).

### 54.3.2 Protein C

Protein C is a major anticoagulant and deficiency is associated with VTE. Protein C is activated by the thrombin/thrombomodulin complex and exerts its anticoagulant action via inactivation of activated factors V (FVa) and VIII (FVIIIa), a process that requires the cofactor protein S (see later). Many mutations have been identified in the gene encoding protein C (*PROC*), which are causal in the development of familial venous thrombosis but are rare in the general population. These rare mutations are beyond the scope of this chapter (see the review by Spek and Reitsma (95) for further information). Three common SNPs in the 5' regulatory region of *PROC* have been identified: -1654 C/T, -1641 A/G and -1476 A/T, which are in close linkage disequilibrium (96), with the -1654 C/T and -1641 A/G and which define the most common haplotypes (CC/GG, CT/AG, CC/AG, CT/AA, TT/AA). These haplotypes associate with differences in plasma protein C, with lowest levels in individuals with the CC/GG haplotype, highest with the TT/AA haplotype and intermediate in the other haplotype groups (97–99). Consistent with this, the CC/GG haplotype associated with increased risk for venous thrombosis in a number of studies (97–99).

A GWAS of variants influencing protein C concentration in the ARIC Study identified 504 SNPs associated with protein C with genome-wide significance ( $p < 5 \times 10^{-8}$ ) (100), with the SNPs most strongly associated with protein C localized to four chromosomal regions, 2p23, 2q13–q14, 7q11.23 and 20q11. The SNP most strongly associated with protein C was rs867186 in 20q11, a nonsynonymous SNP (S219L, also associated with FVII) in the gene encoding the endothelial protein C receptor (*PROCR*, also known as *EPCR*), which accounted for ~10% of variance in protein C. The other most informative SNPs were rs1158867 (2q13–q14), an intronic SNP in *PROC*; rs1260326 (2p23), a nonsynonymous (P446L) SNP in the glucokinase regulatory protein gene (*GCKR*), the same SNP that was associated with variance in FVII (described earlier); rs1714573 and rs1178977 (7q11.23), both intronic SNPs in the gene encoding bromodomain adjacent to zinc finger domain 1B (*BAZ1B*); and rs6120849 (20q11), an intronic SNP in the gene encoding mannosidase alpha-like 2 gene (*EDEM2*). *EDEM2*,

*GCKR* and *BAZ1B* represent novel regulatory genes for protein C, with putative roles in protein degradation, posttranslational modification and transcriptional regulation, respectively; however, each of the SNPs in these genes accounted for <2% of total variance in protein C. Their influence on venous thrombosis is not known.

### 54.3.3 Protein S

Protein S is a cofactor to activated protein C in the inactivation of factors Va and VIIIa. As with protein C, deficiency of protein S is associated with venous thrombosis and mutations have been identified that give rise to rare forms of familial venous thrombosis (see de Frutos et al. (101) for further details (101)). Common polymorphisms of the protein S gene (*PROS1*) have been described, including 2148 A/G (Pro626), 2698 C/A (located 520bp from the termination codon in the 3'-untranslated region) and a T/A polymorphism in intron K (102,103). The Pro626 and the 2698 C/A polymorphisms significantly associate with plasma levels of total protein S antigen, the highest levels in those of AA/AA genotype and the lowest in those of GG/CC genotype (103). It has also been shown that Pro626 is associated with free protein S, a more specific risk factor for venous thrombosis (104). The mechanism(s) by which the Pro626 and 2698 C/A polymorphisms influence plasma levels is unknown; however, the Pro626 polymorphism was not found to be associated with venous thrombosis in relatives of patients with protein S deficiency (105).

### 54.3.4 Antithrombin

Antithrombin is an important anticoagulant factor that inhibits several activated components of the coagulation cascade including thrombin and factor Xa. Deficiency of antithrombin is a risk factor for venous thrombosis and mutations have been identified that account for familial cases of venous thrombosis (106). A number of polymorphisms have also been identified in the antithrombin gene (*SERPINC1*) including a trinucleotide short tandem repeat, (ATT)<sub>n</sub>, in the fifth intron, a -159 T/C polymorphism and silent coding polymorphisms including Asn450, Gln377 and V327 (107,108). The relationships of these polymorphisms to plasma antithrombin concentration or venous thrombosis have not been reported; however, an SNP in intron 1 (rs2227589) has recently been found to be associated with venous thrombosis in the Leiden Thrombophilia Study (109).

### 54.3.5 Tissue Factor Pathway Inhibitor

Tissue factor pathway inhibitor (TFPI) is a heparin-releasable inhibitor of tissue-factor-dependent coagulation and functions by formation of a quaternary FXa/TFPI/FVIIIa/TF complex (110). Decreased plasma TFPI has been associated with both arterial and venous

thromboses (111,112). A number of polymorphisms have been identified that are associated with plasma TFPI, including Val264Met, -287 T/C and -33 T/C (113–115), and in genome-wide linkage analysis the chromosomal region with the strongest linkage to plasma TFPI was in the vicinity of the TFPI structural gene (116). The -287 T/C and -33 T/C polymorphisms have also been shown to influence reporter gene activity and binding of nuclear proteins to suggest they are functional polymorphisms influencing plasma TFPI through effects on gene transcription (117). The -33 T/C polymorphism has been associated with risk of venous thrombosis (115,118).

## 54.4 GENETIC VARIANTS INFLUENCING COMPONENTS OF THE FIBRINOLYTIC CASCADE

### 54.4.1 Tissue-Type Plasminogen Activator

tPA is an endothelial cell-derived activator of the fibrinolytic system that is considered to be protective against thrombotic disorders, a view supported by the clinical use of recombinant tPA following acute MI. In contradiction, however, elevated plasma levels of tPA have been associated with an increased risk of MI in a number of prospective and case-control studies (119,120). The reason for this paradoxical observation is unclear but may reflect the association of tPA with plasma PAI-1 or other risk factors for vascular disease. However, the role of elevated levels of tPA in the pathogenesis of CVD remains unclear at present.

Polymorphisms in the tPA gene include a common Alu insertion/deletion (Alu I/D) in intron 8, and -7351 C/T, -125 T/C, Arg129Trp, 20099 T/C and 27445 T/A (121). There is no association of these polymorphisms with basal tPA levels, although an association with vascular tPA release in a perfused forearm model was found for the Alu insertion/deletion, -7351 C/T, 20099 T/C and 27445 T/A polymorphisms (121–123). Higher release rates were observed in subjects homozygous for the I allele, the -7351 C allele, the 20099 C allele and the 27445 T, relative to those possessing the alternative allele at these sites. The I allele has also been associated with MI in the Rotterdam Study (124), although this has not been confirmed in other studies (25). The T allele of the -7351 polymorphism associated with MI and lacunar stroke (125,126), suggesting that elevated vascular release of tPA in those homozygous for the C allele may be protective against acute thrombosis. In a GWAS analysis from the Framingham Heart Study no SNPs associated with plasma tPA at genome-wide significance (127).

### 54.4.2 Plasminogen Activator Inhibitor-1

PAI-1 is a serine protease inhibitor that is the major circulating inhibitor of tPA. Elevated PAI-1 associates with CVD (128–130) and PAI-1 is found in atherosclerotic

plaques (131). PAI-1 clusters with features of the insulin resistance syndrome (132), which is itself associated with CVD. Common polymorphisms of the PAI-1 gene have been identified, including a 4G/5G insertion/deletion at -675, -844 A/G, Ala15Thr, a CA dinucleotide repeat within intron 3 and a 3' *Hind* III restriction fragment length polymorphism (RFLP) (133). The only consistent associations with plasma PAI-1 have been observed for the -675 4G/5G polymorphism, with approximately 25% higher levels in those homozygous for the 4G compared to the 5G allele (134–136). In vitro studies have confirmed higher rates of transcription associated with the 4G allele and a difference in binding of nuclear factors, with the 4G allele binding an enhancer, whereas the 5G allele binds both an enhancer and a repressor resulting in decreased transcription of the 5G allele relative to the 4G allele (134). As with many gene–disease association studies, a number have reported associations with disease, while others fail to confirm these associations. However, meta-analyses support significant associations of the 4G allele with MI (137) and venous thrombosis (33). In a GWAS in the Framingham Heart Study no SNPs associated with plasma PAI-1 at genome-wide significance (127).

## 54.5 GENETIC VARIANTS INFLUENCING PLATELET FUNCTION

### 54.5.1 Platelet Glycoprotein Receptor Variants

Polymorphisms in the platelet receptors  $\alpha_{IIb}\beta_3$  (GPIIb-IIIa),  $\alpha_2\beta_1$  (GPIa-IIa), GPIb-V-IX and GPVI have been extensively studied in relation to thrombosis. The GPIb-V-IX receptor plays an essential role in primary hemostasis, mediating initial adhesion of platelets under high shear stress to vWF bound to collagen exposed at sites of vascular injury (138), and deficiency of GPIb-V-IX is associated with a bleeding tendency (Bernard-Soulier syndrome). The  $\alpha_2\beta_1$  and GPVI receptors mediate platelet interactions with collagen exposed at sites of vascular injury, with  $\alpha_2\beta_1$  primarily mediating platelet adhesion to collagen and GPVI primarily mediating collagen-induced signaling pathways (139). The  $\alpha_{IIb}\beta_3$  receptor is the final common mediator of platelet aggregation and predominantly interacts with fibrinogen and vWF. Deficiency of  $\alpha_{IIb}\beta_3$  is associated with a bleeding tendency (Glanzmann thrombasthenia) and the importance of  $\alpha_{IIb}\beta_3$  in thrombosis is highlighted by the effective clinical use of anti- $\alpha_{IIb}\beta_3$  agents in the management of acute coronary syndromes (140,141). Polymorphisms in the genes encoding these platelet receptors have been identified and recently reviewed by Williams et al. (142) and are summarized briefly in the following.

$\alpha_{IIb}\beta_3$  polymorphisms include the  $\beta_3$  -468 A/T, -425 A/C, -400 A/C, Leu33Pro and Arg489Gln polymorphisms and the  $\alpha_{IIb}$  Ile843Ser and 10480 C/G

polymorphisms (143). The Leu33Pro polymorphism has been studied extensively, with functional analyses indicating that Leu33Pro does not influence platelet  $\alpha_{IIb}\beta_3$  receptor expression (144). However, Pro33 is associated with a lower threshold for  $\alpha_{IIb}\beta_3$  activation, enhanced  $\alpha$ -granule release, clot retraction and adhesion and binding to fibrinogen (145–147). Haplotypes comprising the -468 A/T, -425 A/C, -400 A/C polymorphisms were shown to influence reporter gene activity but were not associated with  $\alpha_{IIb}\beta_3$  receptor density, although haplotypes comprising these three promoter polymorphisms and Leu33Pro were associated with increased plasma vWF activity, suggesting a potential effect on platelet  $\alpha$ -granule and/or endothelial cell Weibel–Palade body secretion (144). Associations between Leu33Pro and CVD have been described, although results have been conflicting. Meta-analyses have indicated a modest association of Pro33 with an ~10% increased risk for MI (148,149), although this is not consistent in all meta-analyses, as reviewed by Williams et al. (142).

The most extensively studied polymorphisms of GPIb-IX-V in relation to vascular disease are located in the GPIb $\alpha$  gene and include -5 T/C, a 39 base pair variable number tandem repeat (VNTR) polymorphism and Thr145Met (HPA-2) (142). The VNTR polymorphism results in one to four copies of a 13 amino acid repeat sequence within the macroglycopeptide region of GPIb and influences platelet plug formation under high shear rates (150). The Thr145Met polymorphism influences the conformation of the N-terminal region of GPIb $\alpha$  (amino acids 1–59) and binding of vWF (151). The -5 C/T polymorphism lies within the Kozak sequence of GPIb $\alpha$  mRNA and the C allele has been associated with increased receptor density as a result of more efficient translation of mRNA (152). The most extensively studied polymorphisms in  $\alpha_2\beta_1$  are the  $\alpha_2$  Lys505Glu (HPA-5) and the synonymous 807 C/T (Phe224) and 873 G/A (Thr246) polymorphisms (153). The 807 C/T and 873 G/A polymorphisms are in strong linkage disequilibrium and the 807 C and 873 G alleles are associated with lower  $\alpha_2\beta_1$  receptor density (153), with decreased receptor density associated with decreased adhesion to type I collagen (154). There are few reports relating these polymorphisms to vascular disease and the results are conflicting (142); however, an increased incidence of the  $\alpha_2$  807 C allele in patients with Type I von Willebrand disease suggests an association with bleeding (155).

**54.5.1.1 Genome-Wide Association Analysis of Platelet Function.** Moderate to high heritabilities have been reported for measures of platelet aggregation in response to different agonists (156,157), suggesting that additive genetic factors are important determinants of interindividual variance in platelet function. Recent GWAS of platelet function identified a number of novel loci associated with platelet responses (158,159). Johnson et al. (158) identified SNPs localized to three

regions associated with ADP-induced platelet aggregation (1q23.1: rs12566888 in *PEAR1* encoding platelet endothelial aggregation receptor-1; 11p15.4: rs7940646 in *MRV11* encoding murine retrovirus integration site 1 homolog; 7q36.3: rs2363910 in *SHH* encoding sonic hedgehog), three regions significantly associated with epinephrine-induced aggregation (10q25.2: rs4311994 in *ADRA2A* encoding adrenergic  $\alpha_2A$  receptor; 1q23.1: rs12566888 in *PEAR1*; 10q21.2: rs10761741 in *JMJD1C* encoding jumonji domain containing 1C) and one region associated with collagen-induced aggregation (19q13.42: rs1671152 [T323K] in *GP6* encoding platelet GPVI). The genes identified in this study were biologically plausible, encoding either known platelet receptors (*PEAR1*, *ADRA2A*, *GP6*) or intracellular signaling pathways (*MRV11*, *SHH*, *JMJD1C*). Mathias et al. (159) used combined linkage and association to identify genetic loci influencing platelet function at baseline and following 14 days of aspirin treatment in GenSTAR participants of African–American and European American families with a history of premature CVD (159). In linkage analysis, several chromosomal regions showed suggestive linkage with platelet function phenotypes in both ethnic groups, although there was little consistency in loci or phenotypes between the families of European and African descent. The only region of significant linkage was region 5q11.2, which was linked with post-aspirin ADP-induced whole blood aggregation in African–Americans (159). Combined linkage and association analysis identified 31 SNPs significantly associated with one or more platelet function phenotypes; although the majority did not lie in regions with likely candidate genes, SNPs in the vicinity of *MME* (membrane metalloendopeptidase rs1436634), *GLIS3* (GLIS family zinc finger 3 rs10116901) and *IPCEF1* (interaction protein for cytohesin exchange factors 1, also known as *PIP3-E*, rs1534446) were associated with collagen responses, and SNPs in the vicinity of *LDHAL6A* (lactate dehydrogenase A-like 6A rs11024665) and *ANKS1B* (ankyrin repeat and sterile alpha motif domain containing 1B, rs17029861 and rs2373201) were associated with ADP responses (159). There is limited information relating these SNPs and thrombosis. Most convincing evidence supports relationships of the GPVI T323K polymorphism and the strongly linked S219P polymorphism with GPVI intracellular signaling (160) and venous thrombosis (109,161).

## 54.6 GENOME-WIDE ASSOCIATION ANALYSIS FOR THROMBOSIS

### 54.6.1 Venous Thromboembolism

In a hypothesis-driven analysis of associations between ~20,000 SNPs with putative functional roles and DVT, Bezemer et al. (109) identified 7 SNPs that consistently associated with DVT. These SNPs were localized to

*CYP4V2* (ch4, gene encoding cytochrome P450 family 4, 2), *KLKB1* (ch4, encoding prekallikrein), *F11* (ch4, encoding factor XI (FXI)), *SERPINC1* (ch1, encoding antithrombin) and *GP6* (ch19, encoding platelet GPVI). The five SNPs on ch4 were also associated with plasma FXI, with the risk allele for DVT associated with increased FXI in each case (109); adjusting for FXI did not completely abolish associations between each of the SNPs and DVT suggesting potential mechanisms independent of FXI. In a meta-analysis of 28 SNPs in 21 genes previously associated with VTE comprising >120,000 cases and controls Gohil et al. (33) confirmed significant associations of the minor alleles of the following SNPs in hemostatic genes with VTE: factor V Arg506Gln, factor V H2, prothrombin G20210A, prothrombin G11991A, PAI-1 4G/5G, and  $\alpha$  fibrinogen Thr312Ala; in addition, the minor alleles of FXIII V34L and  $\beta$  fibrinogen -455 G/A were associated with protection from VTE. In a GWAS to identify genetic variants associated with VTE, Tregouet et al. (161) identified only five SNPs (rs2420371, rs1208134, rs505922, rs657152, and rs630014) potentially associated with VTE. The rs2420371 and rs1208134 SNPs in the FV gene were in strong linkage disequilibrium with FV Arg506Gln and were not associated with VTE after adjusting for Arg506Gln. The rs505922, rs657152 and rs630014 polymorphisms occur in the *ABO* gene and after adjusting for *ABO* blood group were not significantly associated with VTE (161). The authors additionally applied a candidate gene approach to their analysis by specifically testing associations between SNPs in genes encoding hemostatic factors and VTE and identified rs6825454 in the fibrinogen gene locus (in strong linkage disequilibrium with the  $\alpha$  fibrinogen Thr312Ala and  $\gamma$  fibrinogen rs2066865 polymorphisms) and rs867186 in *PROCR* associated with VTE at  $p < 1 \times 10^{-3}$ . In a recent update to this initial study Morange et al. (162) described an additional association between rs169713, an SNP ~90 kb 5' to the *HIVEP1* gene (encoding a DNA-binding protein involved in transcription regulation), and VTE. The sample size of these studies was relatively small in the context of GWAS and larger studies will be required to identify polymorphic variants associated with more modest increased risks for VTE in the order of 10–20%. In addition, further GWAS analyses of intermediate hemostatic phenotypes are likely to reveal additional polymorphic variants that influence risk for VTE; these analyses are currently underway as part of the Euro-CLOT study (163).

### 54.6.2 Arterial Thrombosis

A number of GWAS have been carried out for CVD, including coronary atherosclerosis, MI and stroke (reviewed by Malarstig and Hamsten (164) and briefly summarized later). Initial GWAS analyses for CVD provided clear replication for a susceptibility locus at

9p21.3, a relatively gene-sparse region of the genome with no obvious candidate genes (165–167). Interestingly, the most informative SNPs in this region are not associated with conventional cardiovascular risk factors (168). However, significant associations between SNPs across the 9p21.3 susceptibility locus and measures of platelet aggregation in response to collagen and epinephrine and also with coronary artery calcification have been identified; however, no clear mechanism has been identified to explain the observed associations (169). A 2011 study compared patients with angiographic evidence of CAD with and without MI to delineate the genetic factors predisposing to the development of atherosclerosis and those leading to plaque rupture and thrombosis (170). The locus most strongly associated with MI in this study was *ABO*, with SNPs tagging non-O blood groups associated with CAD with MI but not CAD alone (170). *ABO* blood groups influence carbohydrate structures on vWF, which influence vWF clearance and plasma levels of both vWF and FVIII, which are lowest in individuals of blood group O (171). Therefore, the associations between *ABO*, venous thrombosis and MI may result from decreased plasma vWF and FVIII, conferring protection from thrombosis.

## 54.7 HOW DO WE ACCOUNT FOR THE MISSING HERITABILITY?

Perhaps the most striking observations from GWAS analyses of intermediate phenotypes for arterial and venous thrombosis is the minor proportion of variance (or risk) explained by the individual SNPs despite the strong genetic component estimated for many phenotypes in twin and family studies. This is an area of much recent debate (172) and in the remainder of this chapter we will consider potential explanations for the discrepancy between heritability estimates and the total genetic contribution suggested by GWAS studies. Evidence from GWAS studies supports a contribution of many genetic variants, with minor individual effect sizes, to the pathogenesis of venous and arterial thrombosis. Studies to date have focused on the identification of novel genetic variants with the strongest associations above a predefined genome-wide significance  $p$  value. For the most part studies have excluded SNPs with  $p$  values below this threshold even in the face of supporting biological evidence indicating the potential for a functional role for a variety of SNPs. Several methods have been recently proposed that enable greater interrogation of GWAS data to evaluate the potential additive contributions of multiple genetic variants to variance in intermediate phenotypes (173) and disease end points (174,175); through these approaches a greater proportion of the heritability for various traits could be accounted for by genotyped SNPs, although a significant proportion of heritability remains unexplained. These methods have yet to be applied to GWAS data

for intermediate hemostatic risk factors for venous and arterial thrombotic disease.

For the most part GWAS studies have not analyzed haplotypes, gene/gene interactions or the combined effects of genes and environment despite a wealth of evidence that migrants attain the cardiovascular risk of the country to which they migrate rather than retaining that of their country of origin, emphasizing the importance of environmental factors. Although genetic variants identified by GWAS have yet to be evaluated, there are numerous examples in the literature that highlight the importance of both gene/gene and gene/environment interactions in modulating hemostatic intermediate phenotypes; a few examples are outlined below to illustrate the concepts more clearly.

The genetic architecture of venous thrombosis is less complex than that of arterial thrombosis and gene/gene and gene/environment interactions have been described in relation to risk for venous thrombosis conferred by the FV Arg506Gln polymorphism. Interactions between Arg506Gln and prothrombin 20210 G/A, oral contraceptive use, pregnancy, air travel and rare inherited disorders of protein C, protein S and antithrombin have all been described (176–180). For example, in the study by Legnani et al. (178) the relative risk (RR) for thrombosis in carriers of Gln506 was 10.3, for carriers of the 20210A allele was 4.7, whereas the RR for those that carried both the Gln506 and 20210A alleles was 45.6. Similarly, the RR for use of oral contraceptives was 4.1 but the risk associated with oral contraceptive use for those that carried both the Gln506 and 20210A alleles was 86.5.

Work from our group has shown that the influence of the FXIII Val34Leu polymorphism on clot structure (determined by analysis of clot permeability) is modulated by fibrinogen concentration and this may influence susceptibility to venous and arterial thrombosis. In subjects homozygous for Val34, clot permeability was found to decrease with increasing fibrinogen concentration, indicating the formation of a denser clot structure with increasing fibrinogen. In subjects homozygous for Leu34, there was no difference in clot permeability with increasing fibrinogen concentration, and intermediate results were obtained for subjects heterozygous for Val34Leu (181). These results therefore indicate that possession of the Leu34 allele would be expected to be protective for thrombosis (relative to the Val34 allele) only in the presence of high fibrinogen. In addition, a significant interaction between Val34Leu and the  $\alpha$ -fibrinogen Thr312Ala polymorphism has been identified in relation to pulmonary embolism, with the apparent protective effect of Leu34 being lost in the presence of the Ala312 allele (64). This finding was supported by in vitro data indicating that the influence of Ala312 is also modulated by fibrinogen level, with a greater decrease in clot permeability with increasing fibrinogen being observed for subjects possessing Ala312, which may counteract the beneficial

effect of Leu34 at high fibrinogen concentrations (181). These studies highlight the importance of considering the accumulated risk conferred by possession of multiple risk alleles and environmental risk factors in evaluating individual risk for VTE.

Gene/gene and gene/environment interactions have also been reported for a number of polymorphic variants that contribute to arterial thrombosis. Plasma PAI-1 levels significantly correlate with plasma triglyceride level and a 4G/5G genotype-specific response to triglyceride has been reported, with the highest levels of PAI-1 being observed in subjects with 4G/4G genotype and high plasma triglyceride levels (182,183). A triglyceride responsive region has since been identified within the PAI-1 5' region adjacent to the 4G/5G site (184). Furthermore, plasma PAI-1 demonstrates diurnal variation and this appears to be related to the 4G/5G genotype, with the most pronounced diurnal variation observed in subjects with the 4G/4G genotype (185,186), linking impaired fibrinolysis with diurnal variation in risk for arterial thrombosis. We have also shown that patients with MI who possessed the Leu34 allele had higher plasma levels of PAI-1 and an increased prevalence of the PAI-1 4G/4G genotype compared with those homozygous for the Val34 allele (187). These findings suggest that the FXIII Leu34 allele is protective for MI unless there is coexistent suppression of fibrinolysis occurring in association with genetic and environmental factors associated with elevated PAI-1.

For a comprehensive review of the impact of gene/gene and gene/environment interactions in studying complex diseases the reader is directed to a review by Wade (188). In this review the issue is succinctly summarized by the statement “although the human genome consists of ‘only’ 30–40,000 genes, this number of genes permits 450–800 million two-gene interactions to say nothing of the myriad of possible multi-locus interactions.” The majority of GWAS studies described earlier have focused on considering one or two SNPs with the highest *p* value rather than evaluating the haplotype structure of the genes in the vicinity of the most strongly associated SNPs. However, many genes have several polymorphic variants that are associated with the phenotype of interest at genome-wide significance and analysis of the haplotype distributions may be more informative where this is the case. A haplotype is defined as the combination of alleles for different polymorphisms that occur on the same chromosome (189), and for any given stretch of chromosomal DNA an individual will have two haplotypes, although at a population level there may be numerous haplotypes for any given stretch of chromosomal DNA. Since haplotypes can extend over many kilobases of a chromosome, haplotype analyses may also reveal informative gene/gene interactions. For the GWAS studies, analysis of haplotype structures and interactions between environmental factors and the genetic factors that predict variance in hemostatic factors and thrombosis (both single

variant, single gene and gene/gene interactions) are yet to be evaluated. Analysis of the cumulative effect of gene/gene and gene/environment interactions will most likely be a major focus in the GWAS community in the next few years and may help to reveal the true extent to which individual genetic factors contribute to estimated heritabilities.

It is also important to understand the methodological issues that may impact identifying genetic variants that influence hemostatic intermediate phenotypes and thrombosis and perhaps more importantly in identifying gene/gene and gene/environment interactions. These include consideration of sample size, population stratification and poorly defined phenotypes that can have a profound influence on the outcome of genetic analyses. While recent extensive international collaborations have resulted in sample sizes sufficient to detect genetic variants conferring an increased risk in the region of 10% or greater, the impact of poorly or inconsistently defined phenotypes (both intermediate and disease end points) is perhaps of greater issue in these large consortia. In this context, it remains unclear how large a sample size would be required to evaluate adequately potential gene/gene and gene/environment interactions.

### 54.8 IMPACT OF GENETIC RISK FACTORS ON THE CLINICAL MANAGEMENT OF THROMBOSIS

In concluding this chapter, it is important to consider how knowledge of the role of common polymorphisms in coagulant and anticoagulant genes has influenced (or will influence) clinical management of thrombosis. In relation to arterial thrombus, it is clear that knowledge of an individual's genotype has had no influence on management, perhaps in part because of the complexity of the disease. Although FV Arg506Gln strongly associates with VTE, a similar situation exists in relation to management of venous thrombosis. What seems most important is to evaluate the total risk profile of each individual, whether a venous thromboembolic event was sporadic or precipitated by a known event such as surgery, whether the event was a first or recurrent event and whether there is a strong family history. Even in the face of such knowledge it is still not clear whether knowledge of an individual's genetic makeup would influence their subsequent behavior or their clinical management. For instance, should knowledge of a woman's genetic makeup be used to influence the decision to prescribe oral contraceptives, particularly when reporting a personal or family history of venous thrombosis? The increased risk of unwanted pregnancies associated with alternative forms of contraception and the increased risk of VTE in pregnancy highlights that this is not a simple decision. At present, despite compelling evidence for a role of common genetic variants in influencing susceptibility to VTE, there seems to be no consensus as to how information regarding

genetic risk factors should be utilized clinically (190). The current absence of evidence that treatment strategies are influenced by knowledge of thrombophilia genotypes or evidence that such knowledge influences lifestyle choices to modulate risk for VTE suggests it is likely that this debate will continue.

### Biographies

**Peter Grant** is a Consultant Diabetologist in the Leeds Acute Teaching Hospitals Trust, with a particular interest in management of vascular risk in patients with diabetes. He is also professor of Medicine and Head of the Division of Cardiovascular and Diabetes Research within the Faculty of Medicine and Health at the University of Leeds. The Division consists of approximately 50 researchers including clinical academic cardiologists and diabetologists, postdoctoral staff and PhD students. He has a current grant income of ~£3.3m, including a British Heart Foundation Programme Grant and funding for two senior clinical fellowships.

The mission of the Division is to understand the molecular basis of the strong biological link between diabetes and cardiovascular disease and professor Grant's major research theme in this strategy is the genetic and environmental determinants of thrombotic risk in relation to insulin resistance and cardiovascular disease. This has included case-control family and twin studies and he has published over 200 original articles in international peer-reviewed journals including those in *Diabetes*, *Blood*, *Circulation* and *The Lancet*.

Professor Grant is editor-in-chief of the international journal, *Diabetes and Vascular Disease Research*, which is a new peer-reviewed journal referenced on medline that publishes research that links these two common conditions.

**Angela Carter** is a principal research fellow in the Division of Cardiovascular and Diabetes Research at the University of Leeds. Her research is focused on the identification and functional analysis of genetic and environmental risk factors for cardiovascular disease with a particular emphasis on the interactions between haemostatic and inflammatory cardiovascular risk factors and their influence on thrombosis.

**Kristina Standeven** is a research fellow in the Division of Cardiovascular and Diabetes Research at the University of Leeds. Her research focuses on the regulation of the end stage in hemostasis, including genetic and environmental factors leading to posttranscriptional and posttranslational modifications in fibrinogen and their impact on structure and function of blood clots.

### ABBREVIATIONS

ALOX5AP – Arachidonate 5-Lipoxygenase-Activating Protein  
 ANGPTL3 – Angiopoietin-like 3 protein  
 BP – Blood pressure  
 CAC – Coronary artery calcium  
 CAD – Coronary artery disease  
 CHARGE – Cohorts for Heart and Aging Research in Genetic Epidemiology  
 CHD – Coronary heart disease  
 cIMT – Carotid intima-media thickness  
 CNV – Copy number variation  
 CRP – C reactive protein (CRP)  
 CVD – Cardiovascular disease  
 dKO – Double knockout  
 eQTLs – Expression quantitative trait loci  
 FH – Familial hypercholesterolemia  
 FLAP – 5-lipoxygenase (5-LO) activating protein  
 GerMI – German MI  
 GLGC – Global Lipids Genetics Consortium  
 GWAS – Genome Wide Association Studies  
 ICAM-1 – Intercellular adhesion molecule-1  
 ICBP – International Consortium for Blood Pressure  
 IL6 – Interleukin-6  
 LpPLA2 – Lipoprotein-associated phospholipase A2  
 LRP6 – low-density lipoprotein receptor-related protein 6  
 MI – Myocardial infarction  
 OR – Odds ratio  
 PDE-4D – Phosphodiesterase 4D  
 QTL – Quantitative trait locus  
 vWF – von Willebrand Factor  
 WTCCC – Wellcome Trust Case-Control Consortium

### 55.1 INTRODUCTION

Atherosclerotic cardiovascular disease (CVD) and its major clinical manifestation, coronary heart disease (CHD), are common conditions responsible for one in three deaths in the United States claiming more than

2200 lives every day (1). While there are many established risk factors for CHD, both acquired and inherited, it is thought that a sizeable proportion of the causality of CHD is heritable. Estimates of the heritability for CVD range from 30% to 60% (2,3) with some studies suggesting that a number closer to 60% may be more accurate, including one large ( $n > 20,000$ ) twin study that used over 30 years of follow-up data (4).

Such studies make a strong case for family history as a robust risk factor for premature CHD and have been reaffirmed in numerous population-based studies including INTERHEART (5) and the Framingham Offspring Study (6). In the latter, those who had at least one parent with premature CHD had a 1.7–2.0-fold increased risk of CHD compared to those without a family history (6). Nevertheless, we are still only beginning to understand how to translate the heritability of CHD into novel prevention strategies and personalized therapeutics.

Much has changed since the last edition of this chapter, with the emergence and maturation of genome wide association studies (GWAS) and the initiation of exome and whole genome sequencing in cardio-metabolic disease. Indeed, the past five years have been paradigm shifting with discovery, through GWAS, of more loci for CHD than identified in the previous 50 years. This, however, may only represent the tip of the iceberg. Further discoveries as well as functional and clinical translation are expected to continue to accelerate and ultimately lead to substantial prognostic and therapeutic advances in clinic. As with other diseases (type 1 and type 2 diabetes mellitus, macular degeneration, and so forth), recent genomic findings are starting to redefine the pathogenetics of human atherosclerosis (see Chapter 86). There is a current intense focus on identification of causal genes at novel CHD loci identified through GWAS, definition of directional effects of loss of function and gain of function in human and animal model systems for genes within CHD loci, exome sequencing

for rare coding variants, development of therapeutics based on these novel genomic discoveries, and nascent advances in risk prediction and personalized genomic medicine for CHD.

This chapter will review recent advances and discoveries, discuss continued challenges to studying the genetics of CVD, and highlight ongoing efforts that will drive continued rapid evolution of the genomics of atherosclerosis and CHD.

## 55.2 CHALLENGES TO GENETIC STUDIES OF CHD

### 55.2.1 Heterogeneity of the Disease Traits

Despite being a common disease overall, there are numerous challenges researchers must overcome to unlock the genetic determinants of CHD. The first is that the CHD phenotype is quite heterogeneous and encompasses a broad variety of conditions. In general, it can encompass any disease related to the heart vessels, of which there are many. These include acute coronary syndromes due to a ruptured plaque within an epicardial coronary vessel, chronic progressive atherosclerosis causing vessel lumen narrowing and/or outward remodeling of coronary vessels, coronary artery dissection, and microvascular coronary disease, to just name a few. For the purposes of this chapter, we focus on genetics or heritability relating to the process of atherosclerosis of the coronary arteries, resulting in chronic ischemic heart disease or acute coronary syndromes. Even within this more limited definition, differences in heritability may exist by location of disease within the coronary tree. For example, some studies suggest that proximal coronary artery disease, including left main disease, may be more heritable compared to distal disease (3,7).

**55.2.1.1 Late Onset Disease.** Because atherosclerosis is not usually evident until clinical events occur in middle or older age, use of classical family studies along generations is difficult. Youngest members of generations may not express detectable atherosclerosis for many years. Relatives in the oldest generations may have died without clear cause or without sufficient documentation to be certain that atherosclerosis was involved. While this means that CHD-related genes are more likely to become passed on to offspring, it may be difficult to discover cases for family-based studies, except in the most extreme cases with early onset CHD. For population-based studies, identifying true controls (those who will not develop the disease at a later date) may also be difficult for a late onset disease unless older individuals are chosen as a control population. Thus, population-based association studies—whether genome wide or candidate gene—have typically used large number of cases who are relatively young and controls who are older.

### 55.2.2 Non-Mendelian Inheritance and Gene–Environment Interactions

Only a small proportion of CHD is monogenic with Mendelian inheritance patterns. In the overwhelming majority of cases, CHD is considered to be a complex trait with multiple genes and gene–environment interactions that contribute to the phenotype. Furthermore, the risk factors for CHD are also polygenic. Even apparent environmental risk factors, such as tobacco use (8,9), also have complex gene and gene–environment basis further impacting the overall complexity of downstream atherosclerosis and making the genetics of atherosclerotic phenotype more difficult to study. Multiple old and recent studies have reviewed the genetics of common CVD risk factors such as dyslipidemia (10–14), the presence of type 2 diabetes (15), and elevated blood pressure (BP) (16,17) showing their heritability in many cases to be complex. These risk factors are the subject of additional chapters in this text (Chapters 52, 86, and 96).

**55.2.2.1 Use of Surrogate Phenotypes.** The study of CHD and atherosclerosis is further complicated by the widespread use of surrogate phenotypes that are commonly used to represent CHD such as follows: atherosclerotic coronary artery disease (CAD) burden seen on coronary angiogram, amount of coronary artery calcium (CAC) seen on cardiac CT, or the degree of carotid intima-media thickness (cIMT) as seen with carotid ultrasound. These phenotypes may act as markers for clinical events such as myocardial infarction (MI) or cardiovascular death; they also may be indicative of the different pathophysiologic consequences of atherosclerosis and each has different strengths and limitations compared to using clinical events alone when studying CHD. For clinical events, it is important to consider the complexity of the underlying athero-thrombotic processes even when focused on an apparently homogenous phenotype such as early onset MI, for example, our group has examined angiographic CAD sub-phenotypes and found that almost all recently identified GWAS loci that associate with MI do so through a relationship to coronary atherosclerosis, while few associate with MI *per se* in the presence of established CAD (18). Such heterogeneity in phenotypic associations has implications for how discovered loci might be used in risk prediction and in therapeutic targeting (e.g., for prevention of atherosclerosis or in reducing plaque rupture or thrombosis).

It is crucial, therefore, to define the CHD phenotype under study, strive to reduce clinical heterogeneity, and to appreciate the potential clinical relevance and translation. At the same time, it is important to recognize that recent GWAS discoveries were successful largely because they used the largest sample sizes possible and did not focus excessively on narrow phenotyping. Simply stated, sample size and power overcame phenotype heterogeneity in these initial GWAS discoveries. Moving forward, particularly with sequencing technologies, a focus on

extreme phenotypes and more homogenous phenotypes may provide powerful insights into the genetics of specific CHD traits.

### 55.2.3 Translation of Animal Model Discoveries into Humans

Human translation of discoveries in animal models of atherosclerosis has been challenging. Mouse models have become the predominant animal model for CHD over the last several decades using both endogenous genetic manipulation and environmental manipulation through diet-induced hypercholesterolemia. This has facilitated testing pharmacologic and genetic hypotheses; however, there also have been many inconsistencies regarding the role of specific pathways (19). These are discussed in more detail later in this chapter.

### 55.2.4 Overcoming the Challenges

Ultimately, it is likely that many different combinations of genetic risks interact with the environment, with chance, and with each other in different ways among individuals, families, and populations giving rise to the heterogeneity of CHD phenotypes. As such, a combination of different techniques including animal models, GWAS, family studies, and whole-exome and whole-genome studies will be needed to help further clarify individual rare and common genetic contributions and their interactions with each other and environmental factors. Finding the genetic contributions that overlap between risk factors (e.g., lipid traits) and CHD phenotypes (e.g., acute coronary syndrome) has only recently become possible with the application of large GWAS, and these should be further elucidated through sequencing-based discoveries.

## 55.3 MOUSE MODELS OF ATHEROSCLEROSIS

The genetic and molecular mechanisms of atherosclerosis have been elucidated, in part, by mouse models although significant caveats will be outlined below. In rodent models, over 100 different genes have been shown to affect atherosclerosis. There has been a significant disconnect, however, between the large phenotypic differences for individual genes in mouse models and their weak or absent associations with atherosclerosis and CHD in humans. With recent gains in human genetics, it is now possible to start to reconcile some of these discrepancies, and it is hoped to move toward more informed and sophisticated application of mouse modeling of this human disease.

Because wild-type mice on a chow diet are not susceptible to atherosclerosis, three main mouse models have been used for examining atherosclerosis: (1) cholesterol-cholate diet or the “Paigen Diet,” which induces enough hypercholesterolemia in wild-type mice to induce

atherosclerosis (20–22); (2) the low-density lipoprotein receptor knockout (KO) mice (*Ldlr*<sup>−/−</sup>), which lacks the primary receptor for LDL cholesterol leading to hypercholesterolemia and atherosclerosis (23) on a Western-type diet; and (3) apolipoprotein-E KO mice (*Apoe*<sup>−/−</sup>), which lack a key lipoprotein for uptake via hepatic lipoprotein receptors leading to marked hypercholesterolemia and atherosclerosis on a chow diet (23–25). In addition, transgenic models (especially for genes not present in mice, e.g., CETP), bone marrow transplantation, and approaches utilizing antibodies or small molecule inhibitors have been used in the wild-type and KO models above to model-specific genes and proteins (26,27).

### 55.3.1 Candidate Gene Approach Using KO Mice

This has been the most popular approach with candidates chosen based on basic biology and human biomarker association as well as on often questionable human genetic associations. Using mouse models, almost always backcrossed onto either the *Apoe*<sup>−/−</sup> or *Ldlr*<sup>−/−</sup> background to generate double knockout (dKO) mice, there are at least 100 genes in published literature with reported significant differences in atherosclerosis in mice. Of these, around one-third also significantly affected total plasma cholesterol levels. Thus, the mechanism of affecting atherosclerosis is likely through lipid-induced pathways, while approximately two-thirds affect atherosclerosis but do not affect plasma cholesterol levels (Table 55-1). These latter genes are mostly candidates chosen for their hypothesized functions in endothelial cells, vascular smooth muscle cells, and specific leukocytes, particularly mechanisms that modulate directly vascular signaling and inflammation. Overall, these candidate gene studies have provided remarkable mechanistic insight into the role of specific lipoproteins and lipid genes and pathways as well as endothelial cell, monocyte-macrophages and T-cell (28) signaling, and inflammatory pathways in experimental atherosclerosis. Although biased in selection, the ratio of lipid to non-lipid candidate genes is somewhat surprising because the traditional thinking has been that atherosclerosis is primarily a lipid disease.

### 55.3.2 Unbiased Mapping in Mouse Models

Mice have also been used to try to identify atherosclerosis genes through unbiased mapping, for example, quantitative trait locus (QTL) analysis (see Chapter 5) (29,30). So far, over 40 mouse atherosclerosis QTLs have been mapped (31), typically analyzing second (F2) generation progeny of two different progenitor strains, one prone to and the other protected against the disease, applying one of the three atherosclerosis models

Supplemental Table 55-1 References.

<sup>a</sup>The knockout is homozygous unless otherwise indicated as heterozygous by '(+/-)'.<sup>b</sup>Positive studies are those with  $p < 0.01$  for cases compared to controls for atherosclerosis effects and  $p < 0.05$  for effects on plasma cholesterol.Adapted from Stylianou, I. M.; Bauer, R. C.; Reilly, M. P.; Rader, D. J. Genetic Basis of Atherosclerosis: Insights from Mice and Humans. *Circ. Res.* 2012, 110 (2), 337–355.

described above. Because the linkage regions implicated in these QTLs are wide and contain hundreds of genes, there has been limited success in identifying the culprit genes. In fact, only three genes have been identified. The *Ath1* locus on mouse Chr 1 (32) was identified and confirmed in a KO model as tumor necrosis factor (ligand) superfamily member 4 (*Tnfsf4*, also known as *Ox40l*) (33). The *Artles1* locus on mouse Chr 6 was positionally cloned as arachidonate 5-lipoxygenase (*Alox5*) (34) and confirmed in *Alox5*<sup>-/-</sup> mice (35). *Adam17* has been

implicated as possible gene at *Ascla5* locus on mouse Chr 12 (36). Although these are plausible candidate genes in humans, there remains uncertainty. In KO mice, the region could carry from the donor strain not just the KO gene but also polymorphisms in regional genes (so-called “passenger gene” effect (37)) that affect the phenotype leading to a false conclusion that the KO gene is solely responsible for the effect (37,38). For example, although human genetic data do implicate *ALOX5* in atherosclerosis, this has not been convincingly proven

particularly in current GWAS data. *CXCL12*, which is associated with human CAD in GWAS, maps to mouse Chr 6 less than 1Mb away from *Alox5* within the so-called “passenger gene” region of the *Alox5*<sup>-/-</sup> strain; thus, polymorphisms in *Cxcl12* might be a significant contributor to the *Artles1* QTL.

### 55.3.3 Challenges with Mouse Models

Mice have proven extremely powerful in studying genes and loci that affect atherosclerosis. However, translation of these findings to human CHD has been slow and unconvincing, partly due to lack of human genetic data. On the other hand, the limitations of mouse models may be much more substantial and pernicious than previously recognized. It is apparent from recent human GWAS that there is almost no overlap with rodent KO or QTL models even now that over 30 loci for human CHD have been identified. Although, some loci in mouse models may indeed contain genes for human atherosclerosis and may emerge in future work (e.g. larger GWAS, pathway analysis, exome sequencing), many are likely to lack relevance to human CHD. It is therefore important to enumerate the potential limitations of prior mouse modeling so that they can be avoided or minimized in future functional translation.

The key issues include (1) the need to create models with extreme hypercholesterolemia in order to induce atherosclerosis—this may be a particularly non-physiological model for the study of non-lipid candidate genes, which appear to be more abundant than lipid genes based on recent human GWAS; (2) lack of homology between mouse and human for genes of interest (e.g. CETP is not expressed in mouse and the 9p21 locus, a major human GWAS discovery, is markedly different between human and mouse); (3) biased candidate gene selection for KO studies in mice due to lack of human data (now no longer the case); and (4) the failure of linkage and mapping strategies in mice. Moving forward, a more human-translational strategy might be worthwhile with mouse studies focused largely on validated human loci and genes, the requirement that there be reasonable genetic homology between mouse and human, and a renewed effort to apply new and improved models when studying human genes, particularly with less extreme lipids.

## 55.4 CANDIDATE GENE STUDIES IN HUMANS

Using the candidate gene approach, polymorphisms in specific genes with plausible biological relevance (based on rodent studies and basic biology, genes from promising family studies, genes in pathways related to proven CHD genes (e.g. lipid pathways), and more recently genes for CHD risk factors arising from GWAS) have been genotyped in populations to determine association with atherosclerosis and CHD and traits. The rationale is

that there should be numerous genes underlying the susceptibility to atherosclerosis in the general population, each with predicted small effects (39).

Indeed, prior to the GWAS era, there were hundreds of specific candidates purported to be associated with premature CAD and atherosclerotic traits, but only a few genes showed a reproducible association with either surrogate outcomes or increased CVD risk. The limitations of prior work included sample sizes and power that were inadequate to detect small but real effects, false positives due to a failure to control for the multiple testing or to replicate findings in independent samples, and, in retrospect, poor selection of candidate genes with many likely not involved or having redundant actions in the human disease. In many cases, candidate gene findings from family-based studies could not be replicated in population association studies (e.g. *MEF2A*), or genes that modulated experimental atherosclerosis in mice did not appear to have relevance in humans (see above), or for some that appeared promising from the mechanistic and causative perspectives (e.g. *MTHFR*), conflicting, and ultimately negative data regarding clinical outcomes during treatment makes such candidates less relevant. The realization of marked false positives in prior publication eventually led to more rigorous design, more cautious interpretation, and ultimately the current relatively conservative approach in the GWAS and post-GWAS era.

The candidate gene approach, however, has revealed a small number of true CAD genes, both lipoprotein and non-lipoprotein related. Based on recent large studies as well as current standards for multiple testing and replication, the list of definite genes, however, is even shorter than that which we had suggested at the last update of this chapter (Table 55-2). For example *LPA* and *PCSK9*, genes for circulating Lp(a) and LDL-C respectively, have reproducible associations with CAD and MI (40–46), subclinical atherosclerosis traits (47–49), as well as their intermediate lipoprotein traits (40,50–53). Indeed, recent Mendelian randomization (see below) studies provide strong support for causal roles of Lp(a) and LDL-C (and related genes) in atherosclerosis and CHD (40–43,50,54–56).

For a substantial set of biologically plausible candidate genes with suggestive evidence in human studies, large studies showing a lack of association have also been reported (57), and thus confidence in those genes remains tenuous. The ITMAT Broad CARE (IBC) 50K CAD Consortium recently completed the most comprehensive study of candidate genes for CAD and MI (57). As a complement to recent GWAS, they conducted a large and systematic candidate gene case-control study of CAD susceptibility, including analysis of many uncommon and functional variants in candidate genes (57). Over 49,000 SNPs, mostly in ~2100 genes of cardiovascular relevance, were genotyped on a custom array in 15,596 CAD cases and 34,992 controls (including almost a quarter of South Asian origin) and replication was attempted in an

additional 17,121 CAD cases and 40,473 controls. Several prior CAD susceptibility loci were confirmed (e.g., LPA, and from GWAS, 9p21.3 and SORT1 at 1p13.3).

Notably, results were essentially negative for most previously suggested CAD candidate genes. Further, apart from the previously reported variants in LPA, none of the other ~4500 low frequency and functional variants showed a strong effect. However, in the replication phase, novel associations were identified for common variants in or near *LIPA*, *IL5*, *TRIB1*, and *ABCG5/ABCG8* with per-allele odds ratios (ORs) ranging from 1.06 to 1.09. Thus, this contemporary large-scale gene-centric analysis identified several novel candidate genes for CAD that relate to lipid and inflammatory pathways, clarified the literature with regard to many previously suggested genes (largely negative), and confirmed some recent GWAS findings (see below).

In an ongoing effort, the National Human Genome Research Institute and several partners have devised the “MetaboChip,” which fine maps all top loci from GWAS of CAD and CVD risk factors (lipids, hypertension, diabetes, obesity, and biomarkers) as well as genotypes all suggestive SNP signals ( $p < 10^{-3}$ ) from those same GWAS (58). The MetaboChip has just completed genotyping in very large case-control samples of CAD and MI. This work will (1) clarify the literature with regard to causal genes and variants at the leading CVD loci suggested by GWAS,

(2) which validated risk factor loci actually do relate to CAD, and (3) by incorporating SNPs from GWAS reaching a lesser  $p$ -value threshold in large focused replication, also overcome GWAS false negatives, an acknowledged limitation of stringent genome-wide Bonferroni correction (59). These latter SNPs will be examined with greater power in the MetaboChip CHD project.

### 55.4.1 Family-Based Studies in Humans

**55.4.1.1 Family-Based Linkage Studies.** In rare instances, atherosclerosis can appear as a Mendelian disorder, such as in familial hypercholesterolemia (FH), where mutations in the LDL-R receptor greatly increase plasma cholesterol and consequently atherosclerosis susceptibility (60). Although largely overtaken by GWAS, family-based linkage studies were deployed quite extensively in the 1990s. Such linkage studies can be considered in three broad strategies: (1) by examining a single very large family under a Mendelian inheritance hypothesis; (2) using several large families in a QTL type approach; or (3) by examining many sibships or trios in families with premature CAD. As with the mouse QTL mapping, the linkage regions using these approaches is typically too large to easily identify plausible causal genes (61). Further, the paucity of strong CAD loci and genes in population samples underscores the weakness of linkage

for common diseases that is to identify rare high-risk alleles, which in reality are infrequent in the population for complex traits. This reality is highlighted by negative results of the largest linkage studies of premature CHD that included 4175 subjects in 1933 affected UK families (62). In at least one large family, however, the Mendelian inheritance approach identified a strong candidate gene in the low-density lipoprotein receptor-related protein 6 (LRP6) (63). This locus as well as additional important examples are described below.

**55.4.1.1.1 Low-Density Lipoprotein Receptor-Related Protein 6 (LRP6).** *LRP6* was identified as the likely causal gene at 12p13 from a linkage study of 28 individuals across four generations of a family with autosomal dominant inheritance pattern of early onset CHD and osteoporosis (63). A missense variant in *LRP6* that segregated with disease was associated with LDL-C, metabolic syndrome features, and other CHD risk factors. The variant was not found in controls.

**55.4.1.1.2 Myocyte-Specific Enhancer Factor 2A (MEF2A).** *MEF2A* is a gene selected from 93 candidate genes in the locus Ch15q26 where a signal was found within a family that had three generations of CHD among 13 members, 9 of whom had an MI (64). *MEF2A* is a gene within this locus that has biological plausibility for a relationship with CHD because of its expression in coronary vasculature in the embryo (64). A seven amino acid deletion was found through re-sequencing of family members with the phenotype and initial functional studies showed this deletion impaired nuclear localization of the *MEF2A* product. However, impaired nuclear localization could not be confirmed in follow-up studies (65) and additional population-based studies showed that while the mutation existed at low frequency, it had no association with sporadic cases of premature MI (66). More recent papers continue to contest the importance of genetic variation in *MEF2A* without a clear consensus, suggesting that potentially other gene(s) in the 15q26 locus may be causative for CVD (67–69).

**55.4.1.1.3 Arachidonate 5-Lipoxygenase-Activating Protein (ALOX5AP).** In work that was transformative for the field, the DeCODE group took advantage of the nationalized medical databases and the detailed genealogical records of family relatedness to perform large population-wide linkage analyses and follow-up association studies of CHD traits in Iceland. Using about 300 Icelandic families, they identified the *ALOX5AP* gene on chromosome 13 encoding 5-lipoxygenase (5-LO) activating protein (FLAP), a leukotriene inflammatory mediator, as the gene underlying approximate 2-fold increase in MI and stroke risk (70). FLAP is important in leukotriene production (70), lipid mediators of inflammation. Such findings have been replicated in other samples, although with weaker effects (71,72) and haplotypes in leukotriene A4 (*LTA4*) hydrolase, a related pathway gene, were also associated with increased MI risk. Using similar approaches, DeCODE also identified phosphodiesterase 4D (*PDE-4D*)

on chromosome 5 as a candidate gene for ischemic stroke (73). However, findings for *ALOX5AP*, *LTA4*, and *PDE4D* have not yet been replicated in MI GWAS studies.

**55.4.1.1.4 A-Type Lamin (LMNA).** *LMNA* has been implicated in multiple Mendelian disorders including cardiomyopathy and lipodystrophy as well as progeria and atherosclerosis. In families with the Hutchinson–Gilford progeria syndrome, both autosomal dominant and sporadic mutations in the A-type lamin (*LMNA*) gene have been identified as causal in premature atherosclerosis and aging (74).

## 55.4.2 Family-Based Association Studies

Family-based association studies provide an elegant approach to studying candidate genes, which overcomes the problem of racial admixture that is a significant concern for association studies of unrelated individuals. In fact, the PROCARDIS consortium demonstrated the feasibility of recruiting a large multicenter sample of parent offspring trios (447 families across four European countries) as well as sib-pairs with premature acute coronary syndrome to perform family-based transmission disequilibrium-based association studies of candidate genes (75). However, such family studies are difficult to recruit and do not overcome the inherent lack of power to detect small effects. Because GWAS of unrelated individuals can more easily recruit large samples and provide methods based on genome wide SNP data to control for population stratification, family-based association studies are less popular and are now mostly used in conjunction with population-based associations studies through meta-analysis strategies designed to increase overall sample size and power. The CARDIoGRAM consortium GWAS of CAD, described in detail below, provides a contemporary example with Framingham and DeCODE Icelandic family data being combined with population-based data for GWAS discovery of heart disease genes.

## 55.4.3 Future Applications of Family-Based Studies

As new techniques such as whole exome and whole genome sequencing emerge, there is renewed interest in family-based studies, independent of the methods of linkage, through combining unbiased sequence data in families with extreme traits with informatic approaches to identify novel genes for CHD traits. In one noteworthy example, Musunuru and colleagues found a novel genetic cause of an inherited lipid disorder by performing whole exome sequencing of family members with extreme familial hypolipidemia—low LDL, TGs, and HDL (76). They found two distinct nonsense mutations in a single gene that co-segregated in affected family members (77). This gene, angiopoietin-like 3 protein (*ANGPTL3*), has been shown in rodents to increase TG and HDL levels

via inhibition of lipoprotein lipase and endothelial lipase (78–81) and was recently identified through GWAS as a locus for plasma lipoproteins and CAD.

## 55.5 GENOME WIDE ASSOCIATION STUDIES

A GWAS is a study where genetic information is obtained for individuals with known phenotypes of interest using a large array of genetic markers. These markers represent common variation in the human genome. The goal of GWAS is to map susceptibility genes by way of detection of associations between the genetic markers and the phenotype of interest (82). GWAS has driven the discovery of multiple novel loci and genes for many complex diseases including CHD. Since identification in 2007 of the Chr 9p21 locus as the first GWAS discovery for CAD, there are now approximately 30 loci for atherosclerotic traits revealed by the GWAS approach (Table 55-3). We provide a brief introduction to GWAS and then discuss findings for CAD and MI.

GWAS are typically designed as case control studies. Because GWAS are focused on common variants, it is not expected that any individual variant will have a very strong association with disease; typically the OR for complex traits is between 1.05 and 1.5. Given the large number of tests and the need to correct for multiple comparisons (typically Bonferroni correction for up to 1 million independent SNPs), large sample sizes (thousands of cases and controls) are required to detect the expected small-to-moderate effects. In addition, a staged strategy has usually been employed whereby a small number of SNPs that reach a pre-specified *p*-value threshold are selected for testing in an additional independent sample. This strategy enhances power (83) and facilitates independent replication while also taking advantage of targeted “look-ups” of top SNPs in existing independent GWAS datasets, thus increasing efficiency and reducing costs. In fact, the most recent wave of secondary GWAS for complex cardio-metabolic traits have typically involved meta-analysis of tens of thousands of individuals (84–88) many of whom were already the subject of smaller GWAS that lacked power to detect anything except the strongest loci. Different populations, may have different linkage disequilibrium structures (89), thus most GWAS are done among homogenous populations. There is continued need to pursue additional GWAS in distinct ethnic groups and to perform replication across ethnicities.

The GWAS approach is not hypothesis driven; rather it is a discovery-based method for detecting novel genetic markers for specific phenotypes. The technique is designed to detect modest association of common variants with complex traits and is relatively unbiased in that a relatively large number of common SNPs are typed with broad coverage across the genome. However, these arrays do not include rare variants and therefore

cannot detect directly effects of stronger disease causing mutations. When a variant is identified that has a reproducible association with CAD, there are several possible explanations: (1) the common causal allele (non-synonymous or regulatory) has a small effect via gene at that locus (e.g. SORT1 locus); (2) the common causal allele has a regulatory effect on gene some distance from the locus (long distance regulatory sites) (e.g., Chr 10q locus downstream of CXCL12); (3) the SNP is in linkage disequilibrium (correlation via common inheritance) with a rarer causal variant nearby at that locus (e.g., LPA SNP); or (4) the SNP is in long-distance linkage disequilibrium with causal variant elsewhere on the chromosome (e.g. likely the case for the Chr 12 pleiotropic CHD locus (90,91)). For a given SNP association, therefore, it is often unclear what is the causal gene at that locus or even if the causal gene resides at that locus.

For many loci, fine mapping and re-sequencing are essential to identify the causal gene even before attempting to establish the direction and mechanism of causal gene relationships. Knowledge of the linkage disequilibrium structure of the region and bioinformatic tools can accelerate such efforts by narrowing the focus on functional elements (e.g. transcription factor binding site, microRNAs, or epigenetic marks) within the locus. Interrogation of expression quantitative trait loci (eQTLs)—that is, SNP associations with mRNA expression (92,93) in disease relevant tissue (e.g. macrophages)—can often be performed *in silico* in existing datasets (e.g. CARDIoGRAM (85)) and point toward causal genes or at least genes in regulated pathways (see Chapter 5).

There are many limitations and precautions when performing GWAS some of which have particular relevance to atherosclerotic CHD and its risk factors. These include (1) the need for very large samples given empiric evidence of small effects; (2) adequate control for population admixture, a cause of confounding especially when using controls that come from different geographic regions than CAD cases; (3) stringent correction for multiple testing (typical *p*-value thresholds of  $<5 \times 10^{-8}$ ); and (4) the need for multiple independent replications, particularly given phenotypic heterogeneity when combining atherosclerotic traits (e.g. CAD and MI). The historical problem of widespread false positives in small candidate gene association studies rightly led to stringent thresholds for genome-wide significance. However, this has led to a significant rate of false negatives where some SNPs with *p*-values between  $1 \times 10^{-3}$  and  $5 \times 10^{-8}$  mark loci that are causal. For example, in GWAS meta-analysis of height, using a maximum likelihood method which makes use of the complete distribution of *p*-values, up to 29% of the phenotypic variance of height could be explained by genetic variants, which was 3-fold higher than using only significant GWAS SNPs (94,95). Strategies for mining these GWAS data in

order to reduce false negatives have yet to become standardized but promise to increase the yield from existing GWAS over time.

### 55.5.1 GWAS Findings for Atherosclerotic Traits

The CVD phenotypes most commonly studied by GWAS are MI, the presence of angiographic CAD, surrogate measures such as CAC and IMT, (96,97) and risk factors for CVD including plasma lipids, hypertension (HTN), diabetes, smoking, and circulating biomarkers. Here we focus on published and emerging data for CAD and MI, for surrogate measures of atherosclerosis and selectively for CHD risk factors and biomarkers. Using GWAS, multiple novel CHD loci have been discovered and replicated (Table 55-2), many of which lack a defined mechanism for their association with CHD. In other cases, loci which were well-known to relate to CHD and its risk factors have been identified from these studies, confirming the utility of GWAS approach. In addition, there has been some overlap between GWAS loci for clinical CHD and those for surrogate measures (e.g. coronary calcium) and for risk factors, particularly plasma LDL cholesterol (86).

**55.5.1.1 The 9p21 Locus.** To date, the Chr 9p21.3 locus is the most well known and reproduced for CHD (both MI and angiographic CAD) in Caucasians although prior to GWAS it was completely unknown in CHD. This locus was first identified almost simultaneously in three studies from the Wellcome Trust Case-Control Consortium (WTCCC), the Ottawa Heart Study, and DeCODE Genetics (98–101) followed by corroboration in almost all subsequent reasonably powered analyses in European ancestry samples (41,54,102). A 2008 meta-analysis, including seven case control studies, found a highly associated SNP within the 9p21 locus (rs1333049), with an OR of 1.29 (95% CI 1.22–1.37) per copy of the risk allele (103). This risk allele is relatively common with ~50% and 25% of individuals of European descent carrying one or two alleles respectively. Thus, this discovery is typical of many in GWAS of complex traits in that it appears to confer a small to moderate effect but, because it is common, it may contribute significantly to the risk of disease in the population (sometimes called the population attributable risk) (89).

Follow-up studies of CHD across a wide spectrum of European ancestry samples have been largely confirmatory (104–106). However, a few studies have been negative (107,108). In particular, those that attempt to discriminate between association with angiographic CAD and risk of MI suggest that the 9p21 locus relates to MI and CHD via coronary atherosclerosis. Indeed, our group found that this locus was associated with CAD defined by presence or absence of angiographic CAD but did not relate to MI among patients with evidence of angiographic CAD, supporting the notion that the 9p21 alleles confer risk of atherosclerosis rather than MI *per*

*se* (18). This concept is indirectly supported by recent work that found significant association of the 9p21 locus with CAC, a surrogate measure of coronary atherosclerosis. In fact, the Cohorts for Heart and Ageing Research in Genetic Epidemiology (CHARGE) consortium, the 9p21 CAD risk allele was the most significant (top SNP rs1333049, meta-analysis  $\beta$  0.269, SE 0.03,  $p = 7.58 \times 10^{-19}$ ) for CAC in a meta-analysis of ~10,000 European ancestry individuals (109). Remarkably, other non-atherosclerotic vascular wall traits, including aortic (110) and intracranial aneurysms (111) have been associated with 9p21 CHD SNPs, suggesting a fundamental role for this locus in several pathophysiologies involving medial arterial remodeling, not just atherosclerosis. Also noteworthy is the lack of association with any traditional risk factors including plasma lipoproteins and hypertension (112–114). To date, studies of cIMT (103,115) as well as aortic IMT (116) and aortic plaques measured at ultrasound (117) have been negative including analysis of carotid ultrasound traits in over 40,000 individuals in the CHARGE consortium GWAS (97). Overall, these data may point toward medial arterial pathophysiologies in its relationship to vascular diseases.

The 9p21 locus association with CAD has been extended to non-European ethnicities including east Asian (Koreans (105), Japanese (115,118,119)), south Asian (120,84), Hispanic, and African-American samples (121). However, the top CAD SNP at the 9p21 locus did vary in some ethnicities, suggesting either distinct causal variants or shared ethnic signals marked by smaller chromosomal regions. For example, the NHLBI CARE Project found modest evidence of replication for the 9p21 locus with CHD in African-Americans but the lead SNP (rs6475606; African-Americans OR 2.0,  $P = 6.4 \times 10^{-4}$ ) was not correlated with the index CAD European ancestry SNP (rs4977574; African-Americans OR 1.18,  $P = 0.17$ ) in HapMap samples of African descent (YRI) ( $r^2 = 0.001$ ) whereas it was in perfect LD with rs4977574 in HapMap CEU ( $r^2 = 1.0$ ). This pattern of fine mapping suggests shared ethnic causal signals marked by a smaller chromosomal region in African ancestry that will facilitate more focused re-sequencing to identify such causal variant(s).

To date, the biology of the association of CVD with the 50–60 kb 9p21 region, containing the CAD risk alleles, has been difficult to elucidate. The closest protein-encoding genes are 100 kb away from these SNPs. In European ancestry samples, there is a large LD block at this locus. At the 3' end there is CDKN2B, encoding a cyclin-dependent kinase inhibitor tumor suppressor, p15<sup>INK4B</sup>, as well as CDKN2A that encodes another tumor suppressor, p16<sup>INK4B</sup>. These kinases are cell cycle regulators of TGF- $\beta$ , which in smooth muscle cells is implicated in aortic aneurysms (122,123) and plays a role in atherosclerosis in experimental models (124). CDKN2A/B may therefore be directly involved in the association with CVD. Notably at the GWAS region, there is a predicted non-coding RNA designated ANRIL,

which encodes multiple microRNA isoforms expressed in vascular cells that regulate target genes, including CDKN2A/B, relevant to vascular homeostasis and disease (125,126). Visel and colleagues have knocked out the orthologous 70-kb non-coding interval on mouse chromosome 4, creating mice that are viable, but which have increased mortality and decreased expression of CDKN2A/B, suggesting loss of a regulatory element for these genes. Furthermore, they showed that cultures of aortic smooth muscle cells from these mice had excessive proliferation and diminished senescence (127).

Others have identified an enhancer hot-spot in this GWAS region that can impact inflammatory pathways involved in CVD. Harismendy and colleagues found marked enrichment of enhancers within the 9p21 region and that two CHD risk allele SNPs disrupt binding of STAT1 and related INF gamma signaling in endothelial cells (128). Overall, the 9p21 locus is a major reproducible GWAS discovery for vascular diseases that appears to act via completely novel molecular and pathophysiological actions. Remarkably, four years on since its discovery, we still do not understand the precise genetic or molecular mechanism of its association, have not yet defined loss of function or gain of function alleles and their impact, and have enabled little work on therapeutic translation.

**55.5.1.2 Additional GWAS Loci for CHD.** Since 2007 and the identification of the 9p21 locus, there have been significant advances particularly in 2009 and 2011 (18,84,85,99,100,110,129–132) (Table 55-3). In 2007, Samani and colleagues combined data from the WTCCC and German MI (GerMI) studies to replicate the 9p21 locus and to identify an additional five putative loci for CAD and MI (100). Kathiresan and colleagues extended these findings in a 2009 report of 2967 early MI cases and 3075 controls replicating six prior findings and identifying three novel loci (110). Simultaneously, additional loci were reported increasing to 13 the total number of replicated CAD and MI loci (43,132). A recent wave of larger studies, most involving meta-analysis of several independent GWAS (18,85,98,130), has increased to over 30 the number of independent genes and loci associated with human CAD and MI. We performed two parallel but complementary multistage GWAS of angiographically defined CAD in order to discover loci related to coronary atherosclerosis distinctly from those associated with MI in the presence of atherosclerosis (18). Using this approach, we identified variants in *ADAMTS7* on Chr 15 as a locus for coronary atherosclerosis whereas *ABO* genotypes, which were surrogates for the loss-of-function O blood group, conferred protection from MI in patients with established CAD.

The CARDIoGRAM consortium, which combined through meta-analysis 14 published and unpublished European ancestry GWAS of CAD and MI including 22,223 cases and 64,762 controls with replication in 56,682 additional individuals, replicated almost all prior loci while identifying and replicating 13 new regions including *ADAMTS7* and *ABO* (85). Work by the

CD4 Consortium, published simultaneously, combined GWAS data across European and South Asian ancestry studies ( $n = 8424$  Europeans and 6996 South Asians with 15,062 controls, replication in 21,408 cases and 19,185 controls). Like CARDIoGRAM, C4D identified the 9p21 locus, *ADAMTS7* at 15q25, *SORT1* at 1p13 but also reported consistent findings across ethnicity and identified four additional loci including SNPs in the lysosomal acid lipase A (*LIPA*) gene at 10q23, *PDGFD* on 11q22, *BCAP29* on 7q22, and *KIAA1462* on 10p11 (84).

## 55.5.2 GWAS of Subclinical Atherosclerosis Traits

CAC and cIMT are two widely studied non-invasive measures of subclinical atherosclerosis. Recent guidelines support use of both measures in the clinic for risk prediction and prevention of CHD (133,134). CIMT is an ultrasound measurement of thickening of the intima and media layers of the carotid artery at specific locations along the common carotid artery (common cIMT) or internal carotid artery (internal cIMT). Both abnormal thickness and the presence of non-obstructive carotid plaque have been shown in multiple independent studies to predict CHD events and stroke (135,136). CAC, measured by cardiac CT is also strongly associated with CHD events (137–139).

The CHARGE consortium recently completed the first comprehensive GWAS of three carotid artery phenotypes, carotid plaque, and both internal and common cIMT among 31,211 subjects across nine population-based studies (97). They found three independent loci for common cIMT that met genome-wide significance: rs11781551 at 8q24 near the *ZHX2* gene, a member of nuclear homodimeric transcriptional repressors; rs445925 near *APOC1* on 19q13, a locus which also includes *APOE*, *APOC2*, and *APOC4*; and rs6601530 at 8q23.1, within *PINX1*, a telomerase inhibitor (Table 55-4). Two loci met genome-wide significance for plaque: rs17398575 at 7q22 near the *PIK3CG* gene, which encodes the PI3/PI4-kinase family of genes and rs1878406 on 4q31 near *EDNRA* or endothelin receptor type A, which has been associated nominally with BP (140), atherosclerosis (141), and CHD (142) in candidate gene studies. The latter SNP region also had quite a strong association ( $p = 2 \times 10^{-6}$ ) with CAD in CARDIoGRAM data. No SNPs achieved genome-wide significance for internal cIMT and none of the genome-wide significant SNPs for MI and CAD in CARDIoGRAM had a significant association with any of these carotid phenotypes (85).

The CHARGE consortium also conducted a meta-analysis across 9961 subjects from five cohorts with significant findings for CAC. As noted, the 9p21 region was rich in SNPs with genome-wide significance for CAC. A second notable finding was on 6p24 locus within the *PHACTR1* gene (top SNP  $p = 2.65 \times 10^{-11}$ ), which also reached genome-wide significance in several GWAS of

**TABLE 55-4 Genome-Wide Significant Loci<sup>a</sup> Associated with CAC and cIMT**

Phenotype	Locus	Probable Causal Gene(s)	Top SNP	P-value <sup>b</sup>
CAC	9p21	CDKN2A CDKN2B, ANRIL	rs1333049	$3.33 \times 10^{-24}$
	6p24	PHACTR1	rs9349379	$3.90 \times 10^{-22}$
Common cIMT	8q24	ZHX2	rs11781551	$2.4 \times 10^{-11}$
	19q13	APOC1 APOE, APOC2, and APOC4	rs445925	$1.7 \times 10^{-8}$
Carotid plaque	8q23.1	PINX1	rs6601530	$1.7 \times 10^{-8}$
	7q22	PIK3CG	rs17398575	$2.3 \times 10^{-12}$
	4q31	EDNRA	rs1878406	$6.9 \times 10^{-12}$

<sup>a</sup>Only genome-wide significant loci are shown ( $p < 5 \times 10^{-8}$ ). Data is taken from studies by the CHARGE consortium (97) and O'Donnell and colleagues (109).

<sup>b</sup>P-values represent those for discovery and replication combined but were genome-wide significant in discovery phase as well.

MI and CAD (85,110). Of all, CAD-related SNPs in CARDIoGRAM, seven had associations with CAC after Bonferroni correction for a significant  $p$ -value being less than  $1 \times 10^{-3}$  (109).

### 55.5.3 Summary of Atherosclerosis-Related Loci

To date, 29 loci for CAD, MI, or subclinical atherosclerosis have met genome-wide significance in large-scale GWAS (Table 55-3). It is worthwhile to briefly review the current knowledge for these loci and related genes. Only a minority of GWAS loci are significantly associated with established CHD risk factors such as plasma lipids, diabetes, or HTN. Several appear to have more pleiotropic effects on diverse disease traits (e.g. ABO, Chr 12). Some loci contain genes, such as *LDL-R* and *LPA* that previously were implicated in atherosclerosis through specific causal pathways and candidate gene studies. Recently, data emerged implicating genes and specific mechanisms for novel loci in atherosclerosis; for example, *SORT1* (143,144).

Some markers, however, are in gene deserts and most have no relation to known risk factors for CHD, contain genes with unknown function, or have described functions that lack obvious mechanisms to account for the association with CAD. One theme that may be emerging is that some loci encode transcription factors, regulatory domains, and signaling proteins that are expressed in vascular cells suggesting direct effect on atherosclerosis. Regardless, these GWAS discoveries point to an emerging paradigm shift in our understanding of the causes of atherosclerosis and have prompted an unprecedented focus on as yet unidentified mechanisms and pathways for atherosclerosis and MI independent of traditional risk factors. Several novel loci have been studied to varying extents and here we will review briefly a few examples that have emerging mechanistic data in atherosclerosis.

**55.5.3.1 Chr 1p13 Locus (SORT1).** The 1p13 locus has genetic and functional data that support its association with CAD and MI. It is both a LDL-C and CHD-associated locus. Homozygotes for the major alleles have a

40% increased risk of MI and increased LDL levels. A non-coding SNP, rs12740374, is likely causal. This SNP creates a C/EBP transcription factor binding site and modulates liver expression of *SORT1* which encodes the sortilin-1 protein. Levels of sortilin are higher in heterozygotes than homozygotes for the major allele. *SORT1* modulates hepatic VLDL secretion and may also regulate hepatic LDL clearance (143). However, the relative role of *SORT1* on production vs. clearance in regulating LDL remains to be defined; this pathway appears to have clear potential as a drug target.

**55.5.3.2 Chr 1p32.2 (PPAP2B).** The rs17114036 SNP is located in the *PPAP2B* (*LPP3*) gene, which encodes lipid phosphate phosphohydrolase 3 (*LPP3*). LPPs are membrane proteins that dephosphorylate lipid phosphates (145). Different LPPs perform distinct functions depending on cell localization and substrates (146), suggesting that novel lipid metabolites may exert an important role in atherosclerosis. Targeted disruption of *PPAP2B* in the mouse results in embryonic lethality due to developmental vascular defects (147).

**55.5.3.3 Chr 6q23.2 (TCF21).** *TCF21* (also named *POD-1* or *Capsulin*) encodes a basic helix-loop-helix transcription factor. Two transcript variants encoding the same protein have been found for this gene (148). *TCF21* is a tumor suppressor gene whose product regulates mesenchymal cell transition into epithelial cells. It is frequently lost in human malignancies (149,150). Expression of *TCF21* marks the spiral septum of the heart and progenitor cells that give rise to the pericardium and coronary arteries (151). It is also expressed in vascular smooth muscle cells (152,153).

**55.5.3.4 Chr 9q34.2 (ABO).** The ABO (transferase A, alpha 1-3-N-acetylgalactosaminyltransferase; transferase B, alpha 1-3-galactosyltransferase) gene encodes proteins for the first discovered blood group system, ABO (154). ABO blood groups reflect the presence of three main carbohydrate antigens and distinct glycotransferase activities: A, B, and H. Individuals with the A, B, and AB alleles express glycosyltransferase activities that convert the H antigen to the A antigen or to the B antigen. The

O blood group, with unmodified H antigens, is caused by a deletion of guanine-258 near the N-terminus, which results in a frameshift and a protein lacking glycosyl-transferase activity (154,155).

Associations of the ABO blood groups with plasma lipoproteins (156) and CHD were reported several decades ago (157–159). In a recent meta-analysis, Wu et al. found a pooled ORs of 1.25 (1.14–1.36) for MI in non-O relative to blood group O carriers (160). ABO-related thrombosis is believed to be mediated by A and B glycosyltransferase-modification of von Willebrand Factor (vWF) resulting in impaired proteolysis and higher circulating vWF and Factor VIII (161). However, ABO also modifies multiple glycoproteins on endothelium and platelets. Remarkably, multiple GWAS have now identified ABO as a locus associated with VTE (162), plasma vWF and Factor VIII (163), plasma LDL-C (164), and sitosterol (165), inflammatory risk markers E-selectin, P-selectin and sol-ICAM1 (166–168), and angiotensin-converting enzyme (169).

The mechanisms underlying how different ABO groups affect CHD and other CVD risk traits remain unknown probably because studying glycobiology is more challenging than studying nucleic acids or proteins (170). Furthermore, there is a lack of appropriate mouse models for the human ABO locus (171). Overall, ABO is notable because of its diverse genetic disease associations and because it highlights a potentially important role of glycobiology in human CVD.

**55.5.3.5 Chr 10q11 (CXCL12).** The only novel CAD GWAS loci related to a known inflammatory gene is the 10q11 locus which is downstream of the chemokine (C-X-C motif) ligand 12 (CXCL12) gene, previously called stromal cell derived factor 1 (SDF-1). The CAD-associated SNPs at this locus are in a gene desert with CXCL12 located ~100,000 bases away. CXCL12 has two common splice variants and up to six additional coding variants. Preliminary data suggest that the 10q11 CAD-associated SNP, rs1746048, is associated with circulating CXCL12 levels and higher transcript levels of CXCL12  $\alpha$ -isoform in human natural killer cells and the liver (172).

Human data remain conflicting as to whether CXCL12 is pro- or anti-atherogenic (173). It is likely, however, that differential tissue-specific roles may be involved, that mice may differ from humans, and that acute vascular injury models may differ from chronic atherosclerosis models. CXCL12 plays a role in angiogenesis and has anti-inflammatory properties, preventing the accumulation of leukocytes in inflamed tissue (174). KO mouse data (Cxcl12<sup>-/-</sup>) suggest that deficiency is detrimental to health as it is required for B-cell lymphopoiesis, myelopoiesis, correct formation of the ventricular septum (175,176), and T-cell development (177). Tissue-specific deletion and over-expression of CXCL12 and the GWAS region in mice, as well as sequencing and functional genomics in humans, will be needed to clarify the biological effect of LOF and GOF alleles in atherosclerosis and MI.

**55.5.3.6 Chr11q23.3.** This locus includes several apolipoprotein genes, APOA5, APOA4, APOC3, and APOA1, as well as ZNF259, the zinc finger protein 259; ZPR1. The lipoprotein genes have greatest mechanistic support for being candidates in atherosclerosis, however, which specific gene or genes remain uncertain. ApoA5 decreases plasma triglycerides by enhancing lipoprotein lipase-mediated triglyceride hydrolysis (178). ApoC3 has opposite effects on plasma triglycerides due to inhibition of triglyceride hydrolysis (179,180). ZNF259 is a mitogenic protein that interacts with tyrosine kinase receptors, including the epidermal growth factor receptor (181) raising the possibility of a functional role in atherosclerosis.

**55.5.3.7 Chr 15q25.1 (ADAMTS7).** The protein encoded by the ADAMTS7 gene is a member of the ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) family. Members of this family have a similar domain organization, including a prepro-region, a reprolysin-type catalytic domain, a disintegrin-like domain, a thrombospondin type-1 (TS) module, a cysteine-rich domain, a spacer domain without cysteine residues, and a COOH-terminal TS module (182,183). ADAMTS are important targets of PTHrP signaling and participate in the degradation of cartilage extracellular matrix proteins (184,185). ADAMTS13 is the protease that cleaves vWF, and mutations in ADAMTS13 cause thrombotic thrombocytopenic purpura (TTP, OMIM: 274150). Many ADAMTS proteins are known to bind and cleave proteoglycans found in the arterial wall including aggrecan, versican, and brevican (186). Indeed, several lines of evidence link the ADAMTS family with atherosclerosis (187–189) and human CVD (189,190).

ADAMTS7 binds and cleaves cartilage oligomeric matrix protein (COMP), an interaction thought to play a role in the progression of arthritis (183). More recently, ADAMTS7 over-expression was shown to increase post-injury neointimal formation in a rat carotid artery balloon-injury model (191). Subsequent knock down of ADAMTS7 expression by topical application of siRNAs decreased post-injury neointimal formation. Over- and under-expression of ADAMTS7 also increased and decreased primary VSMC migration, respectively (191). Overall, human genetic and rodent experimental data suggest that ADAMTS7 is likely to be atherogenic, perhaps through enhanced VSMC infiltration and migration in plaques. These results suggest that ADAMTS7 may be a potential target for therapeutic intervention.

## 55.6 GWAS FINDINGS FOR CVD RISK FACTORS

A complementary strategy for discovery of novel CVD genes is through an indirect GWAS discovery focus on CHD risk factors (86). For loci with reproducible GWAS associations with a specific risk factor, a candidate gene approach (initially with less stringent multiple testing criteria than applied in unfocused GWAS) can be used to

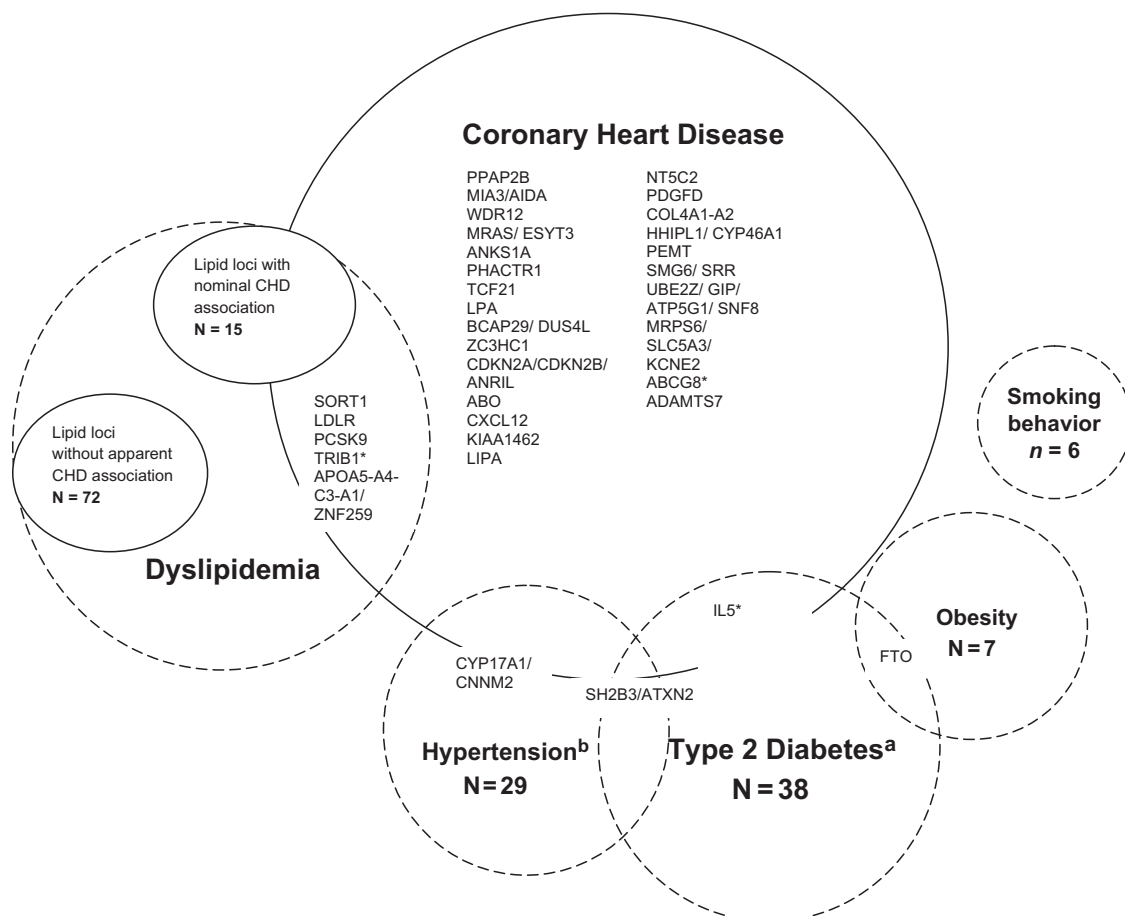

assess whether that locus is also related to CAD and MI. Based on risk factor association, the prior probability is higher and focus is narrower and therefore the chance of discovery of true CHD loci is increased. A related human genomic strategy, Mendelian randomization (see below), also provides a powerful tool under certain circumstances to prove or disprove if a specific risk factor/biomarker for CHD is actually causal. Below, we provide a brief discussion of GWAS for specific CHD loci. **Figure 55-1** presents an overview of which specific loci for specific CHD risk factors, discovered through GWAS, actually also have evidence for association with CHD.

### 55.6.1 GWAS of Plasma Lipids

The genetics of plasma lipoproteins is covered elsewhere (Chapter 96), but we will summarize the most relevant findings for GWAS of plasma lipids as these have proven to be remarkably informative in advancing our understanding of lipid metabolism pathways in CHD. The largest study today by the Global Lipids Genetics Consortium (GLGC) has assembled data on plasma lipid

concentrations for more than 100,000 individuals of European descent and identified 95 significantly associated loci ( $p < 5 \times 10^{-8}$ ), with 59 of these representing completely novel discoveries (86).

Prior lipid loci discovered by smaller GWAS were replicated (41,44,55,106,192,193) and all loci harboring rare mutations that cause Mendelian lipid disorders (e.g., ABCA1, LDLR, and PCSK9) were identified as containing common variation that also associated plasma lipids in the general population. This marked overlap of GWAS findings with Mendelian lipid disorders has provided a form of validation more broadly for the GWAS strategy in complex cardio-metabolic traits and supports the concept that many novel GWAS loci will harbor biologically important genes and rare mutations that cause rare Mendelian lipid disorders. In fact, this has already proven to be the case for ANGPTL3, where rare loss of function alleles are associated with familial cases of extremely low LDL-C, TG, and HDL-C (86). Of the 59 novel loci, 39 were associated with total cholesterol, 22 with LDL-C, 21 with HDL-C, and 16 with TGs.

**FIGURE 55-1** Overlapping loci of CHD and related risk factors from GWAS: <sup>a</sup>These loci were obtained from a large-scale study using the ITMAT/Broad/CARE (IBC) 50k SNP Array (57). <sup>b</sup>Hypertension includes systolic and diastolic blood pressure as well as a history of hypertension. Note: Loci had to meet genome-wide specific threshold criteria for a particular study to be listed in this figure. References include the following: Hypertension (56,205,323), Dyslipidemia (86), Type 2 Diabetes (87), Obesity (324–329), and Smoking Behavior (330–332). Studies for Obesity and Smoking Behavior are less well replicated and validated among large sample size populations and *via* meta-analysis.

The most highly associated locus in the genome for LDL-C was at Chr 1p13, containing SORT1 the causal gene, independently related through GWAS to MI and CAD (41,100) (discussed above). Several loci (e.g. SORT1 (143), MYLIP/IDOL (194), and TRIB1 (144)) have undergone genetic and functional interrogation with definition of causal genes and mechanism of lipid effects as well as initiation of therapeutic programs for targeting these novel genes in lipid disorders and CHD.

A controversial unanswered question for the field is whether genes that relate to HDL-C and TG have equal impact on CHD as loci for LDL-C or whether loci for HDL-C and TG lack systematic effects but rather have gene-specific mechanism-based impact that are only causal for CHD for a limited number of these genes. This would be consistent with some clinical trials and epidemiological literature as well as emerging Mendelian randomization studies (see below). The GLGC data provides an intriguing insight into this question. In 24,607 CHD cases and 66,197 controls, they assessed the relation of the top SNP at each of the 95 lipid loci for association with CAD and MI. Their findings can be summarized as follows: (1) many LDL-C loci had significant associations (corrected for the number of candidate SNPs tested) with CHD and all effects on CHD were in the direction expected based on their relation with LDL-C; (2) most HDL-C and TG loci did not have significant associations with CHD and the observed number with CHD association was barely different from the number expected by chance; and (3) HDL-C and TG loci (e.g., TRIB1) that did have significant association with CHD tended to be those with association with more than one lipid trait. Overall, these data provided strong support for the LDL hypothesis in atherosclerosis, have raised substantial questions regarding the causal association of HDL-C and TG in atherosclerosis (vs. confounding or reverse causation), and suggest strongly that the specific function and mechanism of HDL and TG loci will determine whether they also relate to atherosclerosis and CHD. Thus, therapeutic targeting to lower CHD of genes for HDL-C and TG will remain tentative and restricted to those loci and genes with multiple lipid effects and reproducible human genetic evidence for CHD association.

### 55.6.2 GWAS of Diabetes and Hypertension

Over 30 loci for type 2 DM (Chapter 86) (195–200) and over 25 loci for HTN (Chapter 52) (56,115,195,201,205) have been identified through GWAS, some related to genes that are known drug targets (202). Most loci though are novel and have led to new paradigms in disease pathophysiology, especially for type-2 diabetes where many new loci appear to regulate pancreatic beta cell function. Unlike lipids, there appears to be almost no relationship of type-2 diabetic loci to CHD (Figure 55-1). These diabetic data further support clinical trial

literature in suggesting that most genes for type-diabetes as well as glycemia-diabetes *per se* are not causally related to CHD.

GWAS discoveries for BP and HTN have been challenging due to the dynamic nature of BP and the limitations (e.g., misclassification) of applying the case-control study design to this continuous trait. More recently, particularly through larger studies (203–205) the use of quantitative phenotypes novel loci for BP have been identified. The largest and most recent of these studies completed by the International Consortium for Blood Pressure (ICBP) found, across 200,000 subjects of European descent, 16 novel BP-related loci. Six of these contained genes already known to be related to BP. The ICBP study also confirmed 12 of 13 previously identified loci at the level of genome-wide significance ( $p < 5 \times 10^{-8}$ ) (205). Based upon all significant SNPs from both novel and prior findings, the authors created a genetic risk score, weighted by the average systolic and diastolic BP effect of each SNP. The top decile of risk had a 29% prevalence of HTN and the bottom decile a 16% prevalence. The overall score was quite strongly associated with CHD and stroke (205), but it is not clear yet which HTN loci confer the most risk of atherosclerotic disease. Thus, some BP/HTN loci do relate to CHD and stroke, providing genetic evidence for a causal relationship between BP and atherosclerotic CVD, a finding which is well supported by clinical trials of HTN. As noted already, a few loci (e.g. SH2B3/ATXN2 and CYP17A1/CNNM2) discovered for CAD and MI are also related to BP/HTN providing reciprocal indirect support for causation. In addition to larger GWAS and exome or genome sequencing of extreme HTN phenotypes, an evaluation of each BP/HTN locus for CHD risk is required to determine if there is a systematic association or specific and individual and specific mechanisms of BP gene relationships with CHD. This knowledge combined with functional work may greatly accelerate the translation to clinic for CHD risk prediction and novel therapeutics targeting BP and HTN-related CHD.

### 55.6.3 GWAS of Novel Biomarkers

Many large GWAS of novel CVD biomarkers, particularly inflammatory and thrombotic proteins, have been reported or are ongoing. Some of these biomarkers are not themselves causally related to CHD (e.g. C reactive protein (CRP)), while others may be (e.g. lipoprotein-associated phospholipase A2 (LpPLA2), interleukin-6 (IL6), intercellular adhesion molecule-1 (ICAM-1), and von Willebrand Factor (vWF)). One unanswered question is whether very large GWAS of these markers can reveal novel genes and pathways that are causal for CHD regardless of whether the biomarker itself is or not. Early indications suggest that this may be the case. For example, IL6 and IL6R genes are highly significant in GWAS of plasma CRP levels (206,207) and this cytokine pathway has emerging evidence for causation in CHD. The top GWAS hit for plasma vWF and

Factor VIII is the ABO locus (163) and, as noted, ABO has also been identified in GWAS of MI (18,85).

In addition to a systematic assessment of all biomarker GWAS loci for their CHD relationship in large datasets, specific interrogation in cohort studies using the Mendelian randomization strategy, when appropriate, will provide human genetic evidence for which inflammatory and thrombotic biomarkers are causal in CHD and warrant further focus for therapeutic targeting in CHD. Below, we provide a brief review of Mendelian randomization with some examples related to CHD.

#### 55.6.4 Next Steps for Novel CVD Risk Loci

Each GWAS locus is at a different stage of follow-up investigation, but the majority lack even certainty regarding the specific gene or genetic mechanism and all require genetic mapping and functional work. In general terms, the next steps are to (Figure 55-2) (1) identify the causal gene or genetic mechanism (e.g., non-coding regulatory region); (2) map mutations/causal variation through sequencing and fine mapping; (3) define through functional studies whether the discovered mutations are loss of function (LOF) or gain of function (GOF) for the candidate gene/genetic effect; (4) assess in large human samples whether low frequency LOF or GOF variation increases disease risk in order to understand causal direction of locus on CHD; (5) develop therapeutic translation based on biochemical, functional, and directional characteristics of the gene/locus; and (6) in parallel integrate human genomic data across these loci and future discoveries in order to advance personalized risk assessment in clinical practice (see below).

#### 55.6.5 Mendelian Randomization

This concept has been mentioned above in relation to GWAS of CHD risk factors and discriminating between causal risk factors and non-causal biomarkers of CHD. In this technique, genetic variants are used to help provide evidence that a risk factor/intermediate phenotype is causative for a disease. The intermediate phenotype can be any risk factor under study, such as a biomarker. The genetic variant must directly affect the intermediate phenotype. For example, genetic variants can change the stability of the transcript for the biomarker of interest. If the intermediate phenotype truly causes the disease, then

biomarker-related genetic variants should also be associated with the disease after taking into account the size of the effect of the variant on the intermediate phenotype and the size of the effect of the intermediate phenotype on the disease. This concept is similar to a randomized clinical trial, except here randomization to the exposure (a genetic variant) occurs at meiosis, when genotypes are randomly assigned to gametes. This assignment, being otherwise random, is also free of confounding as each allele as a 50% chance of being transmitted to the zygote. Problems with Mendelian randomization include that the technique is only as good as the estimates of the effect sizes of the variant on the intermediate phenotype and this phenotype on the disease. There is also an assumption that the DNA variant does not impact the disease by other means than the intermediate phenotype of interest (i.e. assumed to be non-pleiotropic). Certain biomarkers, therefore, are unsuited to the Mendelian randomization strategy. Several recent examples for CHD biomarkers are illustrative for this methodology.

**55.6.5.1 PCSK9.** Nonsense variants in PCSK9 that reduce LDL (intermediate phenotype) are observed to be associated with less CHD (disease) in African-American cohorts (44–46). Cohen and colleagues showed that in European populations a common missense variant is associated with 15% lower LDL levels and predicted a 47% lower risk of incident MI. This and other genetic data supports the role of LDL as a causative factor for CHD events.

**55.6.5.2 Lp(a).** The lipoprotein(a) (LPA) story is perhaps one of the better examples of this methodology. For years LPA had been a putative biomarker for CHD and it was unclear whether it was causative. Four major genetic studies have now shown that LPA is causally related to CHD. SNPs at the LPA locus in Europeans are clearly associated with increased LPA levels and higher LPA levels are associated with increased risk for CHD events (40–43,50). These studies showed that individuals with LPA variants causing higher Lp(a) levels are at higher risk for CHD events; a risk that was abolished with adjustment for Lp(a) levels.

**55.6.5.3 CRP.** For CRP, however, Mendelian randomization suggests that there is no causal relationship to CHD and that CRP is more likely a marker for disease *via* reverse causation or confounding. Three large Mendelian randomization studies have not been able to show an association between CRP variants and CHD or

**FIGURE 55-2** Suggested steps for novel GWAS loci. (Adapted from Stylianou, I. M.; Bauer, R. C.; Reilly, M. P.; Rader, D. J.; *Genetic Basis of Atherosclerosis: Insights from Mice and Humans*. Circ. Res. 2012, 110 (2), 337–355).

ischemic vascular disease (106,200,208). Despite this, the use of CRP as a marker for disease may continue to find clinical relevance as it appears to help stratify some patients and direct treatment (209). Nevertheless, finding the etiology or causative component among the inflammatory and risk biomarker pathways is a critical step in determining which specific biomarkers warrant trials of therapeutic interventions to determine efficacy in treating CHD. Mendelian randomization type-studies for other intermediate CHD biomarkers have been completed (e.g. apo E (200,210) and apoA5 (211)) or are ongoing (e.g. homocysteine and IL6/IL6R).

### 55.6.6 Copy Number Variation

Copy number variation (CNV) describes large polymorphic DNA deletions or duplications from 1 kb up to several MB in size, accounting for about 12% of human genomic DNA. CNVs have been associated with specific complex diseases including autism and schizophrenia, but not CAD/MI to date. Indeed, one large GWAS case-control study of early MI by the MI Gen Consortium found no relation of CNVs, defined by about 2 million SNP and CNV probes, despite positive associations of common SNPs with MI in the same sample (44). However, CNVs have been implicated in a vascular wall disorder, sporadic thoracic aortic aneurysm, and dissections (TAAD) that may have some overlap with coronary atherosclerosis pathophysiology (212,213). CNVs in cases with TAAD were enriched for genes regulating cell adhesion *via* interaction with the smooth muscle actin and myosin. Interestingly, mutations in pathway-related genes are reported in those with familial TAAD (212).

**55.6.6.1 Missing Heritability.** Ever since the genome was sequenced, we assumed that we would easily find and explain all of the heritability for CHD traits, which is estimated at 30–50%. In order to provide a similar discrimination as current risk prediction models, it is estimated that at least 20% of the heritability needs to be explained with additive genetic information (214). However, with the totality of information from current approaches and studies only perhaps 10% of the heritability of CAD/MI has been explained (85).

There are several possible reasons for this. First, rare mutations are not covered in GWAS, which focus on common variants. It is these rare variants at known and to-be-discovered risk loci that may impart more severe phenotypes and contribute collectively to a more significant proportion of heritability. Usually these alleles will impart much higher ORs, of disease in those that carry them than the ORs of 1.1–1.3 observed with GWAS-identified common variants. Ongoing and future studies using exome and whole genome sequencing in CHD will identify rare functional variation and with that information we can determine the true contribution to heritability of rare vs. common alleles at risk loci. Second, gene–gene and gene–environment interactions are not accounted for in most

current approaches and likely make up a significant component of CHD risk. Some individuals may be more genetically predisposed to develop CHD if they smoke compared to others. Third, there may be additional unmeasured complex heritability based on tissue-specific epigenetic and transcriptomic regulation, known to have a heritable basis (215). Indeed, the contribution of post-translational proteomic and proteoglycomic modification to heritability of disease traits remains to be studied. Finally, the degree of heritability of CHD may have been overestimated based on older less-powerful datasets and less-sophisticated methodologies. However, it remains likely that at least 30% of CHD traits have a heritable basis.

## 55.7 GENETIC RISK SCORES AND PREDICTION ALGORITHMS FOR PERSONALIZED MEDICINE

A primary goal of determining causative genetic variants associated with CHD is to be able to generate a risk prediction score or algorithm to help personalize CHD risk and inform decisions on treatment. Although often touted as the inevitable product of recent GWAS efforts, this aspiration is arguably the most challenging and will follow the more immediate successes, that is the transformation of our understanding of the causes and pathophysiology of complex CHD and the development of therapeutic programs targeting specific genes.

To date, several nascent attempts have been made to augment traditional risk scores like the Framingham risk score (which does not include family history), or Reynolds risk score (which includes family history and CRP data), as these do not always accurately predict CHD events. For a prediction scheme to be truly successful, clinicians need also be able to act upon the increased risk. For example, moving a high-risk individual to an even higher risk category may not change current treatment regimens, while moving someone from low to intermediate or intermediate to high risk may change treatment and outcome.

Attempts to incorporate the most striking finding from GWAS, the 9p21 locus, into risk predication models have been disappointing. As judged by the C statistic, the addition of 9p21 data to traditional risk factors in one study by Paynter and colleagues did not improve risk discrimination (216). A separate study within the ARIC cohort did show a small increase in the ROC with addition of the 9p21 allele which reclassified 12% of individuals in the low to moderate risk score categories (217). However, one common allele with small effects on a complex trait may add little in predictive modeling. As noted above, some estimates suggest that genetic data accounting for at least 20% of the heritability will have to be used in order to provide substantial discrimination in risk prediction models (214). Thus, use of combinations of independent genetic risk data through additive scores may be

required to improve risk prediction and discrimination at the population level.

Kathiresan and colleagues looked at genotype score combining data for nine (mostly common) SNPs associated with LDL-C and HDL-C and found that this score was an independent predictor of incident CHD in a prospective cohort study after adjustment for traditional RF including plasma lipids themselves (44). However, the score did not improve risk discrimination and only modestly improved risk reclassification beyond standard risk factors. This same research group examined a genetic risk score of 13 common variants, identified by case-control GWAS of MI and CAD, in prospective studies of MI and found small improvements in ROC, discrimination, and reclassification (218). It should not be surprising that we are unable to improve substantially on CHD risk prediction based on current knowledge because, as noted above, only a small portion of the heritable component of CHD has been identified.

In the coming decade, however, there should be exponential advances in risk prediction and personalized preventive medicine. Additional common risk alleles undoubtedly will be identified through even larger and more sophisticated GWAS and candidate genes studies and we have barely started the process of identifying rare, high-impact causal alleles in the existing genomic regions as well as novel CHD loci. In particular, knowledge of rare functional alleles is likely to greatly enhance complex disease prediction and discrimination. Lack of this information is problematic for two reasons. First, inclusion of such data should improve risk prediction and discrimination. More perniciously, use of common alleles without rare allele data introduces substantial potential for measurement error whereby many people with common “risk” alleles that are markers for less frequent disease causing variants are not at any increased risk for CHD if they do not carry the actual rare causal variant.

Current approaches will continue to be limited until such time as we have a more complete picture of all rare and common causal variants across the genome. Such data will emerge through large-scale exome and whole-genome sequencing projects but the task of proving which of the rare alleles are causal remains daunting without a clear, scalable solution. Further, it is possible that the addition of individualized tissue-specific (of greatest relevance to the disease) epigenetic, transcriptomic, proteomic, and other -omic dynamic profiles may add greatly to the assessment of individualized risk over the lifespan of an individual. These developments may evolve rapidly. More likely, however, it will take decades to unlock the potential for genomics to improve personalized medicine.

## 55.8 SUMMARY AND FUTURE DIRECTIONS

Much of the last decade has seen a fundamental shift in the genetic approaches to the study of complex human

diseases. At the start of the last decade, DNA chips and arrays were just beginning to emerge based on the HAPMAP project and nascent knowledge of the human genome. At that time, high-throughput sequencing technologies were still conceptual. Thus, technology and genomic knowledge limited progress. Over the last few years, we have seen the widespread application of GWAS, directly genotyping up to a million SNPs in each individual, in increasingly larger CVD studies. This has led to discoveries of many new CHD genes and the current transformation in how we understand and study atherosclerosis and its clinical complications. However, these are still the early stages in this scientific and clinical journey. Up to now, the GWAS approach has focused on less than 1% of the human genome, which has been biased toward common less-impactful variation and applications have been relatively crude with focus on main effects in case-control studies of end-stage clinical outcomes.

In order to advance clinical practice in terms of therapeutic advances and personalized risk determination, huge genomic efforts as well as mechanistic and translational science needs to be performed. The focus of the next few years will be whole exome sequencing (to identify casual variation in the “lower hanging fruit” of coding sequence), whole genome sequencing (to identify causal variation in the non-coding regulatory genome), and perhaps larger-scale incorporation of whole-transcriptome and epigenome data (to layer on top the tissue/cell specific manifestation of genomic regulation). Moderately sized whole-exome projects in MI and CHD traits are already a reality through NIH-NHLBI-funded efforts such as the Exome Sequence Project of Early Onset MI (ESP-EOMI) and related traits, which should report data in 2013.

Given the large amount of existing and emerging data on CHD loci and genes, there is great need for higher throughput functional modeling in human and animal systems. Scaling rodent and other humanized models of atherosclerosis to provide rapid screening of genes at a given locus and to define the direction of impact of LOF on disease is essential. Yet, animal models may fail to recapitulate the human reality or prove challenging to model the human state as appears to be the case for several emerging loci (9p21, CXCL12, ABO, and others). Thus, there is great need for tools to interrogate tissue-specific function in cells that are directly relevant to the human disease process including endothelial cells, vascular smooth muscle cells, and macrophages as well as hepatocytes and adipocytes. The emergence of human induced pluripotent stem cells (hiPSC) reprogramming technology (219–222) and the ability to differentiate hiPSC to specific somatic cells (223–225) provides the potential to address cell specific function and mechanisms in human for proven common and rare CHD genotypes. It remains to be seen if hiPSC will serve as reliable models, if epigenomic and transcriptomic programs can be fully manipulated to execute full reprogramming and

subsequent complete somatic differentiation, and if full reprogramming is required to recapitulate true primary cell functions (226,227).

The next few years have the potential to fundamentally change current model of human atherosclerosis. The use of high-throughput sequencing, scalable functional studies as well as creative clinical studies, and use of families will define the full spectrum of causal genes and variants. Understanding the effect of LOF and GOF for specific CHD risk alleles will be critical to comprehensive clinical translation in personalized CHD risk and therapeutics. The coming years of human CHD genomics promise to be even more exciting and transformative than the last several when this chapter was previously revised.
